Glossary

Friendship – A voluntary, dyadic peer relationship that is typically characterized by reciprocal liking, preference for each other's company, frequent association or interaction, and a positive affective tie between the partners.

Peer-group acceptance/rejection – A concept that refers to children's relations with members of their peer group (e.g., classmates) and is defined in terms of group member's sentiments (i.e., liking vs. disliking) toward the child, and the degree to which these sentiments become consensual. Measures of this construct indicate the extent to which a child is liked versus disliked by members of his or her peer group (e.g., classmates).

Peer victimization – A form of peer relationship in which children are frequently targeted by peers for verbal and/or physical aggression, or other forms of harassment or abuse.

Attempts to describe the demands of schooling and children's educational readiness suggest that classroom environments present children with a complex array of scholastic and interpersonal challenges, all of which require some degree of adaptation on the part of the child (see Ladd, 2003). These diverse challenges – depending on the child and the resources or constraints that are operating in the child's environment – may affect children on many levels and have both immediate and long-term effects on their development and performance in the school context.

Schooling Presents Children with Social as well as Scholastic Challenges

Some of the most obvious challenges of schooling are scholastic in nature, and stem from the instructional features of classrooms, such as didactic small- and large-group instruction, teacher-initiated/monitored learning activities, and programmatic curriculum sequences. Less well recognized are the many types of interpersonal challenges that children confront in school.

During the transition into formal schooling, children typically are faced with shifting social ecologies,

relationships, and resources. Studies show that, as children enter school, most are thrust into new peer groups with unfamiliar classmates (see Ladd and Price, 1987). As the adult-to-peer ratio is often smaller in classrooms than it is in family or preschool environments, interactions with peers become more common than those with adults, and competition for adult attention increases. Opportunities for mixed-age companionship are rare because, unlike family or neighborhood environments, grade school classrooms are segregated by age. The result is that, once in school, children are under greater pressure to succeed among equals. They must succeed at forming relationships with age-mates while also competing with peers for resources and recognition.

In addition to the demands of the classroom peer milieu, children are confronted with the challenge of forming relationships with their teachers. During the transition to grade school, children often lose ties that were formed with preschool or day-care teachers and embark on a relationship with their grade-school teachers. Initially, this relationship may be a source of care giving, but over time, the teacher's primary role is to challenge children in ways that promote learning and development.

Many of these same challenges are repeated as children progress through the grades. In each new classroom they must negotiate their needs in dyadic and group interactions and reestablish or form new relationships with classmates and teachers. Moreover, it is likely that these challenges are intensified when children change schools, or cope with school transitions (see Ladd *et al.*, 2006).

Do Social Relations Play a Role in How Children Adjust and Perform in School?

Although considerable evidence has been gathered on the precursors of children's school adjustment, most of what has been discovered points to the importance of children's cognitive and linguistic skills, their physical-motor skills, and their socioeconomic and ethnic backgrounds. Only recently have researchers systematically explored children's classroom social behavior and relationships as predictors of their school adjustment. This is surprising when one considers that education is, in many respects, a social enterprise. Most modes of instruction require that teachers and students communicate and engage in social interaction. Likewise, educators have become increasingly reliant on peer-mediated activities (e.g., peer collaboration and

tutoring and cooperative learning groups) to promote classroom learning and achievement.

Fortunately, recent theory and evidence on the interpersonal foundations of learning and achievement has elevated this topic's importance within the educational community (e.g., see Hamre and Pianta, 2001; Ladd, 2003). As a result, greater investigative attention has been devoted to the hypothesis that social relations in the school context may influence multiple aspects of children's school adjustment. In particular, it has been proposed that classroom social relations may be instrumental in shaping children's: (1) perceptions and appraisals of school and the classroom environment, (2) psychological and emotional reactions in this context, including both internalizing and externalizing problems, (3) involvement and disengagement in classroom activities, and (4) achievement and academic progress (see Ladd, 2003).

Are Children's Behaviors with Classmates and Teachers Associated with Their School Adjustment?

It has been postulated that the way in which children behave toward classmates and teachers has an important bearing on how they will adapt to school, and progress academically in this context (Ladd, 2003). A key premise within most of these perspectives is that many of the processes and conditions that are essential for learning, such as curiosity, interest, attention, motivation, perceived support, and feelings of competence and security, develop from the interactions children have with their classmates and teachers.

Most of the child behaviors that have been examined as correlates or antecedents of school adjustment can be classified into three categories, termed withdrawn behavior (e.g., avoiding others; being unsociable), prosocial behavior (e.g., cooperating with others), and aggressive behavior (e.g., harming others). Each of these forms of behavior has been linked with children's early and later school adjustment.

Children Who Avoid, Withdraw from, or Remain Solitary among Classmates

Although early studies produced mixed findings, recent evidence suggests that withdrawn children have difficulty adapting to school (see Ladd, 2005). Several subtypes of withdrawn children have been studied (e.g., asocial-withdrawn, anxious-withdrawn, active-isolated, depressed-withdrawn, and aggressive-withdrawn children; see Harrist *et al.*, 1997; Ladd and Burgess, 1999), and it appears that some forms of withdrawn behavior impose greater risk for school adjustment problems than others. During the grade school years, children who fit the depressed-withdrawn subtype tend to exhibit elevated rates of peer neglect and rejection (Harrist *et al.*, 1997), and children who manifest

stable patterns of anxious-withdrawal exhibit higher levels of depression (Gazelle and Ladd, 2003). Aggressive-withdrawn children also appear to be at risk for several types of school adjustment problems. Ladd and Burgess (1999) followed children who displayed two forms of withdrawal – asocial-withdrawn and aggressive-withdrawn behavior – from kindergarten to grade 2 and compared them to samples of nonwithdrawn-aggressive children and normative, matched controls. Across these grades, children in the aggressive-withdrawn group were more likely than normative, matched controls to become rejected by classmates and form teacher–child relationships that were high in conflict and dependency and low in closeness. The relationship difficulties of asocial-withdrawn children, in contrast, were found to be more transient. These children exhibited more dependent relationships with their teachers as they began kindergarten, but not thereafter.

Children Who Are Prosocial or Aggressive toward Others

Children's propensity to engage in prosocial behavior in the classroom represents another potential determinant of their school adjustment. Ladd *et al.* (1999) found that kindergartners who often interacted prosocially with classmates during the first 10 weeks of kindergarten tended to develop mutual friends and had higher peer acceptance by week 14. Other data show that as early as preschool and kindergarten, aggression is common in classrooms and is a significant predictor of later school adjustment. Ladd and Price (1987), for example, found that children who were aggressive toward many rather than a few classmates in preschool classrooms were more likely to develop social difficulties after they entered kindergarten. Similarly, Ladd and Burgess (1999) found that aggressive kindergartners were more likely than their counterparts in a matched risk-comparison group to develop and maintain social difficulties with classroom peers and teachers throughout the early primary grades.

Even more compelling were findings reported by Ladd and Burgess (2001). These investigators reported that aggressive kindergartners exhibited gains in thought problems, misconduct, and classroom disengagement, and were prone toward underachievement and the formation of negative school attitudes as they progressed into the primary school years. Furthermore, children who tended to be chronically aggressive (i.e., remained aggressive across more than 1 year of grade school) were even more likely to exhibit serious or severe forms of school maladjustment.

Findings from research on middle- and high school children further substantiate the link between aggressive behavior and school adjustment difficulties. For example, Kupersmidt and Coie (1990) followed children from grades 5–10 and found that aggressiveness among fifth graders forecasted higher levels of delinquency among

10th graders, and that both aggression and absences were associated with later dropout rates. Other findings suggest that aggression is a better predictor of dropping out of school for boys than for girls (see Ladd, 2005).

Children's propensities to engage in withdrawn, prosocial, and aggressive behaviors also have been linked with features of the teacher-child relationship. In a longitudinal study, Birch and Ladd (1998) found that children's aggressive behavior in kindergarten predicted higher levels of conflict and lower levels of closeness in their relationships with kindergarten and first-grade teachers. Although kindergartners' prosocial interaction styles were associated with teacher-child closeness in both kindergarten and grade 1, this link was not as robust as that found between aggressive styles and teacher-child conflict.

Are Children's Relationships with Classmates and Teachers Associated with Their School Adjustment?

Another line of research has been guided by the premise that children's relationships with classmates and teachers immerse them in processes (e.g., participation vs. exclusion, support vs. conflict, and receiving assistance vs. being ignored) that affect their ability to adapt to school challenges which, ultimately, affects their development in this context (amount of learning, level of school engagement; increases or decreases their sense of worth, competence, etc.; see Ladd, 2003, 2005). As relationships bring different processes to bear upon children and confer different provisions, they vary in adaptive significance for school-related demands (Ladd *et al.*, 1997). In the next three sections, the adaptive significance of several types of classroom relationships is considered.

Classroom Peer Acceptance and Rejection

A growing corpus of findings link children's acceptance or rejection by classroom peers with indicators of their school adjustment (see Ladd, 2005). Early peer rejection – at school entry – has been shown to predict problems such as negative school attitudes, school avoidance, and underachievement during the first year of schooling and thereafter (Ladd, 1990; Ladd *et al.*, 1999; Ladd and Burgess, 2001). Later, in the elementary years, peer acceptance has been linked with loneliness (Parker and Asher, 1993), conduct problems (Ladd, 2006), lower emotional well-being (Ladd, 2006), and academic deficits (Ladd *et al.*, 1997).

Researchers have also attempted to distinguish the contributions of peer acceptance and rejection from those of other classroom relationships. Ladd *et al.* (1997, 1999) found that, even after controlling for other forms of peer and teacher-child relationships, peer rejection predicted

children's participation in the classroom which, in turn, was linked to later achievement. In a similar study, Buhs and Ladd (2001) found that children's peer acceptance at school entry predicted changes in classroom participation which, in turn, predicted later academic and emotional adjustment. In general, these results support the premise that peer acceptance promotes social inclusion which, in turn, yields provisions (e.g., sense of belongingness and engagement in learning activities) that enhance children's interpersonal and scholastic adjustment (Buhs *et al.*, 2006).

Classroom Friendships

Investigators have studied several indicators of classroom friendships, including children's participation in a close friendship, the number of mutual friends they have in their classrooms, the duration of these relationships, and features that reflect the quality of a friendship (see Ladd, 2005). There is growing evidence linking one or more of these facets of friendship to children's school adjustment.

As children enter school, those who find prior friends or form new friendships in their classrooms tend to form favorable school perceptions and do better academically than peers with fewer friends (Ladd, 1990). The processes that typify friends' interactions have also been linked to children's school adjustment. For example, Ladd *et al.* (1996) detected variability in the quality of the friendships that children formed as they entered school, and found that children who saw their friendships as offering higher levels of support and aid tended to see their classrooms as supportive interpersonal environments. Conversely, children (especially boys) who reported higher levels of conflict in their friendships exhibited lower levels of classroom participation. Likewise, it appears that friends facilitate adjustment as children progress through grade school. Findings from a study conducted with third through fifth graders showed that children with supportive friends felt less lonely in school (Parker and Asher, 1993).

Although less well understood, there is some evidence to suggest that friendships do not always contribute positively to children's school adjustment. Berndt and Keefe (1995), for example, found that fighting and disruptiveness in school tended to increase if adolescents had stable friendships with peers who exhibited the same problems. While far from being conclusive or exhaustive, these studies suggest that, in addition to peer-group acceptance, the features of children's friendships (support, companionship, stability, etc.) are potential antecedents of school adjustment across a wide range of ages.

Peer Victimization

The probability that children will encounter peer abuse, or become the targets of bullying or other forms of peer

harassment, increases as they enter school and progress through the primary grades, and evidence indicates that victimized children develop a variety of school adjustment problems (see Ladd, 2005). It has been posited that frequent harassment leads children to become so preoccupied with fears, feelings of social alienation, and safety concerns that they have difficulty attending to school tasks and, eventually, develop negative school attitudes or higher levels of school avoidance.

During the early school years, children who are exposed to higher levels of peer victimization display increases in loneliness and school avoidance (Ladd *et al.*, 1997), and these difficulties tend to become more pronounced if children are chronically maltreated. Kochenderfer-Ladd and Wardrop (2001) found that children who were exposed to victimization over longer intervals between kindergarten and third grade were more likely to feel lonely in school and less satisfied with their classroom peer relationships. Children who were victimized during the early grades but not thereafter did not always recover, or show improvements in their adjustment. These longitudinal findings have been corroborated by cross-sectional evidence gathered with diverse age groups around the world (see Ladd, 2005). Data gathered in many different cultures suggest that victims of peer maltreatment are more likely than nonvictims to report negative feelings and attitudes toward school and classroom tasks (Ladd, 2005; Ladd *et al.*, 1997). Although further investigation is needed, especially across age groups, gender and school contexts, the bulk of extant evidence conforms to the hypothesis that victimization contributes to a number of school-related difficulties.

Teacher–Child Relationships

It has been argued that close, rather than conflictual or dependent, teacher–child relationships benefit children and support their progress in school (see Birch and Ladd, 1998; Hamre and Pianta, 2001). Evidence gathered thus far shows that, among kindergarten children who were at risk for retention, those who had positive teacher–child relationships were more likely to be promoted than were those with negative teacher–child relationships (Pianta and Steinberg, 1992). Similarly, in a longitudinal study, Birch and Ladd (1998) found that kindergartners with conflictual or dependent teacher–child relationships were more likely to develop later adjustment problems, such as delayed academic performance, lower classroom participation, and negative school attitudes. Ladd *et al.* (1999) also found that qualities of the teacher–child relationship predicted later classroom participation and, indirectly, academic achievement. While these findings have yet to be replicated with older samples and varying demographic groups, available evidence implicates the teacher–child relationship as a potential antecedent of children's school adjustment.

Contributions of Multiple Classroom Relationships in Children's School Adjustment

In recent years, research on individual classroom relationships has been supplemented by studies in which investigators gather data on multiple relationships, and examine the relative (differential) contributions of these ties to children's school adjustment. Initial efforts to investigate differential relationship contributions were focused on friendship and peer acceptance (e.g., see Parker and Asher, 1993).

Studies of grade-school children suggest that classroom friendships and peer-group acceptance make distinct contributions to the prediction of socioemotional adjustment and academic competence (Parker and Asher, 1993). With young children, Ladd (1990) found that friendship and peer acceptance uniquely predicted changes in kindergartner's school perceptions, avoidance, and performance. In another study (Ladd *et al.*, 1997), the contributions of several types of peer relationships were examined after adjusting for shared predictive linkages, and some relationships were found to be better predictors of children's school adjustment than others. Peer victimization, for example, predicted gains in children's loneliness above and beyond associations that were attributable to friendship and peer-group acceptance. In contrast, peer-group acceptance uniquely predicted improvements in children's achievement. Overall, these findings were consistent with the view that peer relationships are both specialized in the types of resources or constraints they create for children, and also diverse in the sense that some resources may be found in more than one form of relationship.

Are Children's Classroom Behaviors and Relationships Distinct or Interdependent Precursors of School Adjustment?

With the advent of child and environment theories (see Ladd, 2003), researchers began to investigate multiple antecedents of adaptation and, in particular, the interface between children's classroom behavior and relationships as predictors of their school adjustment. Although studies of this type are still few in number, extant evidence tends to corroborate the view that children's behavioral propensities combine with their involvement in specific types of classroom relationships (and relationship experiences) to predict school adjustment (see Ladd, 2003). In two prospective longitudinal studies, Ladd *et al.* (1999) found significant, direct paths from children's behavior to their classroom relationships, and from these relationships to their participation in classroom activities, even after controlling for entry factors that are known to predict school engagement (e.g., family backgrounds, ethnicity, child's gender, intelligence quotient (IQ)). The strongest of these paths indicated that aggressive behaviors anteceded the formation of negative classroom relationships (e.g., peer rejection and

teacher–child conflict) and, in turn, these negative classroom relationships functioned as an impediment to children's engagement in classroom social and scholastic activities. In addition, consistent with past research on the antecedents of scholastic progress, direct, positive pathways were found from classroom participation to achievement.

In another longitudinal study, Ladd and Burgess (2001) sought to determine whether aggressive children's participation in different types of classroom relationships might increase (e.g., exacerbate) or decrease (i.e., compensate for) their probability of developing psychological and school adjustment problems. Results implied that aggressive children's school adjustment difficulties became more or less serious depending on whether they were accepted or rejected by their classmates. On the one hand, peer-group rejection was associated with increases in aggressive children's thought problems and decreases in their classroom participation, positive school attitudes, and achievement. On the other hand, peer-group acceptance was associated with relative declines in aggressive children's attention problems and misconduct, and relative gains in cooperative participation and school liking.

In addition, researchers have examined whether children's school adjustment varies as a function of the persistence of their behavior patterns and the stability of their participation in classroom relationships. Ladd and Burgess (2001) assessed the duration of children's risk status for aggression and stressful peer relationships as they progressed through the first 2 years of grade school. Compared to early-onset indicators, the chronicity of children's aggressive risk status across grades predicted changes in a host of school adjustment criteria, including increases in attention problems, thought problems, and behavioral misconduct, and decreases in cooperative classroom participation and academic achievement. After controlling for initial peer-group rejection and the chronicity of children's aggressive risk status and other relational risks, the chronicity of peer-group rejection also predicted many of the same forms of school maladjustment that were associated with aggression. These findings corroborated the inference that the predictive contributions of aggressive behavior to children's school adjustment are exacerbated by chronic relational risks.

Taken together, these findings strengthen the credibility of models in which it is assumed that both behavioral risks and classroom relational experiences affect emerging patterns of school adjustment. In addition to children's actions in the classroom, the relationships they form in this context appear to have an important bearing on their school adjustment.

Conclusions and Future Directions

During the school years, it appears that a number of connections develop among children's classroom behavior,

relationships, and school adjustment. Several are worthy of comment, and warrant further investigation.

Behavioral Precursors of School Adjustment

Available evidence suggests that the behaviors children utilize to address classroom challenges may elicit specific environmental reactions that make it more or less likely that they will learn, adjust, and progress in this context. Pertinent to this inference are findings indicating that children's propensities to withdraw versus participate socially in classrooms, or engage in prosocial versus aggressive behaviors, may impact the level and form of their involvement in classroom relationships and activities and, thus, contribute to their school adjustment.

Children who withdraw from classroom interactions appear to restrict their opportunities to participate in social and scholastic activities, and isolate themselves from resources that can be found in classroom relationships (support, affirmation, aid, etc.). Among withdrawn children, those who have been identified as also being depressed, aggressive, or anxious, appear to be at greatest risk for subsequent school maladjustment. Aggressive-withdrawn kindergartners, in particular, tend to develop social difficulties with classmates and teachers, and experience a variety of school adjustment problems as they progress through school.

Children who frequently engage in aggressive behaviors appear to elicit reactions from peers (e.g., ignoring and exclusion) and teachers (e.g., conflictual interactions) that reduce their constructive participation in classroom activities. Such environmental restrictions may adversely affect learning and achievement, and promote the development of negative attitudes toward school, classroom activities, peers, and teachers. Whereas children with prosocial behavioral styles exhibit positive social and scholastic outcomes during kindergarten and thereafter (e.g., supportive peer and teacher–child relationships and greater engagement in classroom activities), those with aggressive styles are more likely to develop incipient and persistent forms of school maladjustment (e.g., loneliness, peer rejection, teacher–child conflict, and classroom misconduct).

Relational Precursors of School Adjustment

As we have seen, the adaptive significance of children's peer and teacher relationships was also investigated independently and conjointly with children's classroom behavior, and this corpus of evidence implied that classroom relationships have an important bearing on several aspects of school adjustment. Both peer and teacher–child relationships appear to be important in this regard.

Evidence indicates that classroom peer relationships are specialized in the types of resources or constraints they create for children. For example, in contrast to classroom

friendships or peer-group acceptance, peer victimization appears to be a stronger influence on the development of loneliness and school avoidance. Peer-group acceptance, by comparison, appears to have greater sway over children's participation in classroom activities and subsequent achievement.

It also appears that the contributions of peer relationships to children's adjustment depend not only on the functional properties of particular peer relationships (e.g., the resources or constraints they confer upon children), but also on the duration of children's participation in these relationships (i.e., their history of exposure to specific relationship processes). Extant findings indicate that children's risk for maladjustment is increased by longer exposures to relational adversities and decreased by stable relational supports.

Conclusions and Future Directions

Available evidence suggests that both children's behavior toward classmates and teachers, and the relationships they form with these persons, play an important role in establishing the social, intellectual, and psychological conditions that underlie school adjustment and scholastic progress. Ultimately, it is the combination of these processes that appears to be most prognostic of children's school adjustment. Much remains to be learned, however, about the role of children's classroom interpersonal behavior and relationships as precursors of school adaptation and adjustment. Given the complexity of these phenomena, there is a need to construct models that will focus the search for interpersonal antecedents, and provide a context for understanding how these factors impact children's school adjustment. It will also be important to consider not only how specific interpersonal factors exert an influence on adjustment, but also which aspects of children's school adjustment are affected by these factors.

Social Interaction and Learning

K Littleton, Open University, Milton Keynes, UK

Introduction

This article is concerned with how learning and development are assisted by the interactions which take place in schools. More specifically, the focus is on the nature and significance of synchronous, face-to-face educational dialogs in classroom contexts. Psychologists and educators have gained from Piaget, Vygotsky, and the researchers who have extended their work, an affirmation of the value of social interaction for learning and development, whether it be interaction between peers of similar levels of understanding or between people more in the roles of learner and teacher (for reviews see Mercer and Littleton, 2007; Light and Littleton, 1999). Indeed, it has been suggested that any: “efficacious pedagogy should be a judicious mix of *immersion* in a community of practice and *overt focusing* and scaffolding from ‘masters’ or ‘more advanced peers’ who focus learners on the most fruitful sorts of patterns in their experience” (Gee, 2000: 201–202). Mindful of this, this article considers both how teachers use dialog to help children learn and develop their ability to reason and the processes through which knowledge and understanding can develop when learners talk and work together relatively autonomously in classroom settings.

How Teachers Use Dialog to Help Children Learn and Develop

Education is not simply a matter of an individual accumulating information; it involves the gradual development of new problem-solving skills and new ways of using language for representing knowledge and making sense of experience. It also entails the gradual induction by teachers of students into new perspectives on the world. Over the last 30 or so years much research has sought to understand how teachers use talk to guide learning and construct a shared version of educational knowledge – common knowledge (Edwards and Mercer, 1987) – with their students. Drawing on this body of work, Mercer (1995) suggested that teachers use talk to do three things:

- (a) *elicit knowledge from students*, so that they can see what students already know and understand and so that the knowledge is seen to be ‘owned’ by students as well as teachers;
- (b) *respond to things that students say*, not only so that students get feedback on their attempts but also that

the teacher can incorporate what students say into the flow of discourse and gather students’ contributions together to construct more generalised meanings;

- (c) *describe the classroom experiences that they share with the students*, in such a way that the educational significance of those joint experiences is revealed and emphasised. (p. 25–26)

Knowledge Elicitation and Questioning

When attempting to elicit knowledge from their students, in addition to using direct elicitations, teachers very commonly utilize a technique which Edwards and Mercer (1987) term cued elicitation. Cued elicitation is a way of drawing out from students the information that is being sought by providing strong visual cues and verbal hints as to what answer is required. While cued elicitation is often accomplished through asking questions, there has been considerable controversy in educational research concerning the use of questions more generally as a strategy for guiding the construction of knowledge. Specifically, there has been disagreement concerning the functions and value of this characteristic form of classroom interaction (see, e.g., Norman, 1992; Wells, 1999).

At one time it was common to find researchers criticizing teachers for using questions and for talking too much. It was claimed, for example by Dillon (1988) and Wood (1992), that because most teachers’ questions are designed to elicit just one brief right answer (which often amounts to a reiteration of information provided earlier by the teacher) this unduly limits and suppresses students’ contributions to the dialogic process of teaching-and-learning. There was criticism too of the characteristic three-part I–R–F (initiation–response–feedback) structure of classroom discourse. The IRF exchanges open with an initiation, usually in the form of a question, from the teacher which elicits a response from a student, to which the teacher typically provides an evaluative follow up or feedback. The suggestion was, as Skidmore (2006: 507) explains, that the I–R–F sequence results in a quiz which requires students to do little more than display their recall of knowledge got by rote and produces a pattern of teacher-led recitation which tends to reinforce the teacher’s authority as the transmitter of received wisdom and severely restricts the possibilities open to students to contribute thoughtfully to classroom talk.

However, most classroom researchers would probably now agree that such judgments were too simplistic. One reason is that critics did not fully acknowledge

teachers' professional responsibility for directing and assessing children's learning of a curriculum, and that it would be perverse not to rely on questions and other prompts to do so. Second, critics tended to assume that all question-and-answer exchanges were performing the same function. However, the forms of a language do not have a simple and direct relationship to their functions. In the classroom, teachers' questions can thus have a range of different communicative functions. They can, for example, be used:

1. . . . to test children's factual knowledge or understanding . . .
What is the nearest planet to the sun?
2. . . . for managing classroom activity . . .
Could we have all eyes to the board please?
3. . . . and as a way of finding out more about what pupils are thinking . . .
Why did you decide to have just three characters in your play?

Even the above account is an oversimplification, because any single question can have more than one function (e.g., the third question above could be used to find out what pupils know and to get them to attend). Also, a question takes on a special meaning in the context of ongoing events. Compare, for example, the function of asking for the name of the nearest planet to the sun before beginning a scheme of work on the solar system, with asking the same question after it is completed.

The key point is that there is a need to distinguish between form and function when analyzing and evaluating questions in teacher-pupil dialog: and one can only judge the function of questions, and any other forms of language, in dialogic context. With respect to the I-R-F while it can result in the learners' display of recalled knowledge, it can also be used creatively by the teacher to: help students plan ahead for a task they are about to carry out, or to review and generalize lessons learned from the tasks they have already performed (Skidmore, 2006, 507). The teacher's follow up, for instance, can be put to multiple uses – including clarification, exemplification, explanation, expansion, or justification of a student's response. It could also invite a student to do any of those things (Wells, 1999). So while teachers' questioning certainly can require children to guess what answer is in the teacher's mind, that is merely one possible function. Teachers' questions can also serve other very important functions in the development of children's learning and their own use of language as a tool for reasoning. They can: encourage children to make explicit their thoughts, reasons, and knowledge and share them with the class; model useful ways of using language that children can appropriate for use themselves, in peer group discussions, and other settings (such as asking for relevant information possessed only by others, or asking why questions to elicit reasons), and provide opportunities

for children to make longer contributions in which they express their current state of understanding, articulate ideas, and reveal problems they are encountering.

Responding to What Students Say and Describing Shared Classroom Experience

While unsuitable contributions to a classroom-based discussion may be rejected or ignored, one of the ways teachers engage with their students is to use incorporate their contributions into the ongoing teaching-learning process. This is accomplished through confirmation or repetition of things of educational significance (to underscore their salience to the whole class) and the elaboration of contributions to further explain or highlight their significance (Edwards and Mercer, 1987; Mercer, 1995). From a student's perspective, school work should ideally have a cohesive, cumulative quality in which specific activities and their goals can be seen to form part of greater whole, as part of a purposeful educational journey.

Research has identified a number of ways in which teachers try to create continuities in the experience of learners, for example, by referring to past events and implicating these in the joint construction of knowledge with their students. Teachers commonly use recaps to summarize what they consider to be the most salient features of a past event for the current activity (Edwards and Mercer, 1987; Mercer, 1995). Recaps can be literal, when a teacher simply sums up what happens (Last week, we began reading *Macbeth*) or reconstructive, the latter being where the teacher rewrites history, presenting a modified version of events which fits his/her current pedagogic concerns. Teachers also frequently use elicitations to help students' recall of past events (e.g., Who can tell me what they found out about the moon in the last lesson?). It is common too for them to mark past shared experiences as significant and relevant by using *we* statements (as in Remember when we looked at the map of Finland?). In these ways, teachers invoke common knowledge and highlight the continuities of educational experience, trying to draw students into a shared, cumulative, and progressive understanding of the activities in which they are engaged.

Alexander (2000), Crook (1999), and other educational researchers have argued that coherent knowledge and purposeful understanding will not naturally emerge for students from their continuous immersion in classroom life: it has to be pursued actively as a goal, through the use of appropriate teaching strategies. Talk with a teacher, and with other students, is perhaps the most important means for ensuring that a student's engagement in a series of activities contributes to their developing understanding of the subject matter as a whole. In order to understand how classroom education succeeds and fails as a process for developing students' knowledge and understanding, research is now beginning to focus on exploring the temporal

relationship between the organization of teaching-and-learning as a series of lessons and activities and how it is enacted through talk and joint activity (see for example, Mercer, 2008; Mercer and Littleton, 2007; Rasmussen, 2005; Scott *et al.*, 2006). The importance of cumulative, rather than simply extended, dialog is central to the notion of dialogic teaching (Alexander, 2004).

Dialogic teaching

Dialogic teaching is a concept which enables us to focus more precisely on the role of the teacher in classroom talk. The concept has emerged from the comparative, cross-cultural research of Alexander (2000). In some ways, classroom talk sounds very similar the world over; but Alexander's work suggests that there seem to be some, quite subtle, variations in the ground rules which normally apply. Even within countries, teachers can set up markedly different expectations among members of their class about how they should engage in dialog. The variation Alexander describes is not revealed by comparisons of the extent to which teachers use questions or other kinds of verbal acts: rather, it concerns more nuanced aspects of interaction such as the extent to which teachers elicit children's own ideas about the work they are engaged in, make clear to them the nature and purposes of tasks, encourage them to discuss errors and misunderstandings, and engage them in extended, linked sequences of dialog or chains of enquiry about such matters.

Dialogic teaching is that in which both teachers and pupils make substantial and significant contributions and through which children's thinking on a given idea or theme is helped to develop and move forward. It is intended to highlight ways that teachers can encourage students to participate actively in dialogs which enable the students to articulate, reflect upon, and modify their own understanding – and, conversely, how they may avoid doing so. Alexander suggests that dialogic teaching is indicated by certain features of classroom interaction: questions are structured so as to provoke thoughtful answers; answers provoke further questions and are seen as the building blocks of dialog rather than its terminal point and individual teacher–pupil and pupil–pupil exchanges are chained into cumulative, coherent lines of enquiry rather than left stranded and disconnected (Alexander, 2004: 32).

In terms of what the teacher actually does in classroom interaction, dialogic teaching can be characterized as that in which students are given opportunities and encouragement to question, state points of view, and comment on ideas and issues which arise in lessons; the teacher engages in discussions with students which explore and support the development of their understanding of content; the teacher takes students' contributions into account in developing the subject theme of the lesson and in devising activities which enable students to pursue their understanding themselves, through talk and other activity, and

the teacher uses talk to provide a cumulative, continuing, contextual frame to enable students' involvement with the new knowledge they are encountering.

Dialogic teaching is essentially a specification of good practice, derived from both theory of the nature of dialog (drawn from the work of Bakhtin, Vygotsky, and others) and observations of practice across a range of cultural settings. It has clear links, in both its origins and its nature, with some other concepts devised by educational researchers such as reciprocal teaching (Brown and Palincsar, 1989), contingent tutoring (Wood and Wood, 1999), dialogic enquiry (Wells, 1999), and dialogic spells (Nystrand *et al.*, 2003). As an educational concept dialogic teaching is both descriptive and prescriptive. It represents an approach to classroom teaching which: aims to be more consistently searching and more genuinely reciprocal and cumulative (Alexander, 2004: 1) than is usually observed in classrooms, anywhere in the world. Dialogic teaching is that which is collective, reciprocal, supportive, purposeful, and cumulative. It requires a teacher to orientate to the state of understanding of students, engage them in exchanges which will reveal the changing limits and possibilities of their developing interests and understandings, and adjust their communication strategies accordingly as classroom interaction progresses. It involves students taking an active, engaged role in both their own learning and that of their classmates; becoming explicitly part of a collective endeavor. It requires the creation and maintenance of the kind of dynamic intersubjectivity that Mercer (1995) has called an intermental development zone.

It is important to note that Alexander also suggests that some key indicators of dialogic teaching concern the ways in which children are seen to talk and work together in collaborative group settings and he particularly identifies the following as being important: children listen carefully to each other; they encourage each other to participate and share ideas; they build on their own and each others' contributions; they strive to reach common understanding and agreed conclusions, yet they respect minority viewpoints (Alexander, 2004: 33). This characterization of children engaged with each other and each other's ideas is juxtaposed with the seeming paradox of children being seen to work everywhere in groups, but rarely as groups.

Talking and Learning Together

While the study of children's group-based activity in school has had a relatively brief history, there has been a great deal of research interest in children's collaborative working, learning, and problem-solving in more general terms. It is clear that children's joint activity has been researched in diverse ways – for example, through large-scale surveys of life in classrooms; experiments in which pairs or groups of children work on specially designed

problem-solving tasks; and detailed analyses of talk between pairs or groups of children working on curriculum-based tasks in school.

Surveying Classroom Activity

Perhaps one of the first messages to emerge from work surveying classroom activity is that, at least in British primary schools, truly collaborative activity rarely happens. This was the conclusion of a large-scale research project carried out in the 1970s called ORACLE (Galton *et al.*, 1980). The ORACLE team of researchers, observing everyday practice in a large number of British primary schools, found that just because several children were sitting together at a table (as was common) did not mean that they were collaborating. Typically, children at any table would simply be working, in parallel, on individual tasks. This problem has also been underscored in a number of more recent studies, some of which have shown that even when children are set joint tasks their interactions are rarely productive (Galton *et al.*, 1999; Blatchford and Kutnick, 2003; Alexander, 2004, 2005). This tells us something important about the nature of everyday educational practice and leads to the conclusion that if simply left to their own devices to discuss something or talk together much classroom-based talk among children may be of limited educational value.

Experimental Studies

Much of the early collaborative learning research consisted of experimental studies of peer interaction which were designed to establish whether working and solving problems collaboratively was in fact more effective than working alone. Typically, children would be given the same task, but allocated either to working collaboratively or working alone, and their performance on the task assessed. Reviewing such studies, Slavin (1980) noted that cooperative or collaborative learning was often judged to increase students' academic achievement, self esteem, and motivation. These sorts of investigations gave rise to a related strand of research in which independent variables, such as the size of the group (e.g., Fuchs and Fuchs, 2000), group composition, with respect to, for example, gender and ability (e.g., Barbieri and Light, 1992; Howe, 1997; Webb, 1989; see also Wilkinson and Fung, 2002 for a review of work in this field), and nature of the task (e.g., Cohen, 1994; Light and Littleton, 1999; Underwood and Underwood, 1999) were manipulated and attempts were made to assess their effects. However researchers now tend to focus less on establishing parameters for effective collaboration and more on the ways in which factors such as task design or group composition influence the nature of collaborative interaction (Dillenbourg *et al.*, 1995; Littleton, 1999; Kleine-Staarmann, in press). This shift to a more process-oriented kind of

investigation has brought with it an interest in the talk and joint activity of learners working together on a task, with attempts being made to identify those interactional features which are important for learning and cognitive change.

Many experimental studies of collaborative interaction have focused on how children talk together when they are working on a problem or task. In particular, correlational techniques have been used to establish whether there is evidence of an association between particular features of the learners' talk and on-task success or subsequent learning gain as indexed by individual performance on a posttest. For example, Azmitia and Montgomery (1993) found that the quality of children's dialog is a significant predictor of their successful problem solving. Studying children engaged in joint computer-based problem-solving tasks, Barbieri and Light (1992) found that measures of the amount of talk about planning, negotiation, and the co-construction of knowledge by partners correlated significantly with successful problem solving by pairs, and to successful learning outcomes in subsequent related tasks by individuals. Similar analytic techniques used by Underwood and Underwood (1999) demonstrated that for pairs of children working on a computer-based problem-solving activity those who were most observed to express opinions, analyze the situation in words, and express agreement and understanding achieved the best outcomes. Experimental evidence thus supports the view that focused, sustained discussion among children not only helps them solve problems but promotes the learning of the individuals involved. While this may seem like common sense, if it is so obviously true, one is led back to the question raised in the previous section of why high-quality peer discussion is not seen in many classroom contexts.

Researching Talk between Pupils in the Classroom

In the classic work *Communication and Learning in Small Groups* Barnes and Todd (1977, 1995) show how knowledge can be treated by pupils or students as a negotiable commodity when they are engaged in joint tasks. They suggest that pupils are more likely to engage in open, extended discussion and argument when they are talking and working with their peers outside the visible control of their teacher, enabling them to take more active and independent ownership of knowledge. Based on their in-depth observations, Barnes and Todd suggest that classroom discussion has to meet requirements for explicitness which would not typically be required in everyday conversation. Knowledge should be made publicly accountable – relevant information should be shared effectively, opinions should be clearly explained, and explanations examined critically. They also argue that the successful pursuit of educational activity through group work depends on learners sharing the same ideas about what is relevant to the discussion and having

a joint conception of what is trying to be achieved by it. These points have been supported by other research studies (Bennett and Dunne, 1992; Galton and Williamson, 1992; Kumpulainen and Wray, 2002; Mercer and Littleton, 2007).

What Counts as Learning?

Within the research literature on collaborative learning, there is considerable diversity in what is conceived of as learning and as a learning outcome. As indicated earlier, for Barbieri and Light (1992), Underwood and Underwood (1999) and others (such as Howe and Tolmie, 1999) learning is seen in terms of individual accomplishments, demonstrated through appropriate tests on individual children after group activity. Most of that research recognizes that the quality of talk and social interaction is a significant factor. However, the more radical possibility is that collaborative talk is not just a stimulant for individual thinking, but can itself be considered a social form of thinking. As some researchers have put it:

talk and social interaction are not just the means by which people learn to think, but also how they engage in thinking. . . . [D]iscourse *is* cognition *is* discourse. . . . One is unimaginable without the other. (Resnick *et al.*, 1997: 2)

This is a challenge to traditional, individualistic accounts of the nature of knowledge, and of learning. It implies that talk is not just the mediating means for supporting individual development, rather that ways of thinking are embedded in ways of using language. From this perspective, the accomplishment by children of particular forms of educated discourse is a valuable educational goal in its own right. This raises the possibility that how a learner engages and interacts with other learners may have a profound and enduring impact on their attainment and, indeed, on their intellectual development.

Supporting and Promoting Productive Interaction

Many opportunities for collaborative learning are fortuitous. They simply emerge as a consequence of being part of a particular community of learners. That said, we still need to understand how best to enable learners' joint endeavors, so that we can promote the most effective opportunities for collaborative learning and design strategies for optimizing collaboration. This concern is reflected in recent research, in which three factors have been given particular attention: task design; quality of relationships; and quality of talk.

Task design

When thinking about the issue of how to support productive group work many researchers have emphasized the significance of task design. It is important that group tasks

should be designed such that learners need to work together on them. Therefore tasks should not be too simple, for if each child can easily solve the problem or complete the task alone, then there is no imperative for joint working. Equally, if the task is too complex for the children, then they will struggle to create understanding and meaning. A group task is one which requires resources that no single individual possesses and is one in which students work interdependently and reciprocally – the exchange of ideas and information being vital to success (Cohen, 1994). It is perhaps not surprising, then, that some research suggests that open-ended, challenging tasks are more effective in facilitating productive interaction than more closed tasks focused on finding one right answer (Cohen, 1994; Van Boxtel *et al.*, 2000). This is in part because closed tasks more easily lead to one participant, perhaps, a more knowledgeable person, dominating the discussion (Arvaja, 2005). A clear task structure and provision of feedback is also important and this might be one of the best ways in which computer-technology can resource joint activity (Howe and Tolmie, 1999). That said, it is not simply a case of getting the task right. Of course, good task design helps: but because the meaning of educational tasks is created through interaction – task design is only part of the story.

Quality of relationships

According to Van Oers and Hännikäinen (2001: 105): “The main reason why discourses in collaborative learning processes ever lead to improved understandings is that the participants in the process are willing to share their understandings and keep on doing so *despite* their disagreements and conflicts . . . the fact that they can ever be productive at all relies on the fact that the participants in this process, for the time being, feel obliged to each other, stay with each other and maintain togetherness.” This claim draws attention to the importance of the relationship between partners as they interact and work together. Researchers investigating how friendships mediate joint activity (e.g., Azmitia and Montgomery, 1993; Hartup, 1998; Youniss, 1999; Vass, 2003) have found that relational closeness is associated with the sharing of ideas, exchanging points of view, and a collective approach to challenging tasks. It seems that the development of close relationships, characterized by a sense of trust and mutuality, enhances learning (Howes and Ritchie, 2002; Underwood and Underwood, 1999). Findings such as these have led some researchers to argue that what is needed is a relational approach to group working, which properly recognizes that classroom learning is a social activity (Blatchford *et al.*, 2003). The suggestion is that training should be given to promote the development of close relationships between classmates, through among other things, developing interpersonal trust between the children – something which is often stressed in work

investigating collaborative activity in the creative arts (see Miell and Littleton, 2004). To this end, Blatchford and colleagues have developed an educational intervention program which they characterize as using a relational approach to the development of group working. Drawing on influences from attachment theory and studies of parent-child interactions, the program engages the participating children in activities designed to foster trust and mutual support and develop communication skills and joint problem solving. Evaluations of the program involving comparisons between experimental and control classes have indicated that this relational approach is not only successful in motivating children to participate in group activity and value it, but that it has a significant impact on their reading and mathematics attainment (Kutnick, 2005). Work by researchers such as Swann (1992) which highlights that some peer-based interactions are highly gendered and are characterized by dominance and asymmetry also add weight to the claim that for group activity to be effective children need to be taught to relate in positive ways.

Quality of talk

Other researchers, such as Mercer and Littleton (2007), suggest that children have to do more than engage with each other in a positive and supportive way; they also should become able to build constructively and critically on each others' ideas. It is their assertion that it is imperative to teach children how to use language to reason together. In collaboration with colleagues, they have developed Thinking Together, a classroom-based approach which places a special emphasis on the role of the teacher as a guide and model for language use, who fosters an inclusive climate for discussion while also enabling children to understand better how language can be used as a tool for thinking. It supports children in learning to talk in groups as well as providing them with opportunities for talking to learn. Through the systematic integration of both teacher-led interaction and group-based discussion children are helped to understand that aims for group activity and the use of spoken language are as much to do with high quality educationally effective talk and joint reasoning through exploratory talk, in which reasoning is accountable and visible, as with curriculum learning. The processes by which children learn how to learn are thus directly addressed, rather than being left to chance. The approach is more than delivering a particular form of communication skills training. It does encourage children to engage in particular ways of talking and working together, and they are explicitly guided in how to use language as a tool for reasoning together. They are encouraged to give reasons, seek clarification, ask questions, listen to each others' ideas, and so on. But children learn much more than a model set of talk strategies, and the goal is not that they will simply adhere to the ground rules for such talk. The main goal is children's active appropriation of

a particular educated way of talking and thinking, one that they understand and appreciate, so that in time they are able to apply, adapt, and develop their use of language flexibly and creatively in their discussions. Evaluations of the approach undertaken with children across a diverse age spectrum shows that teachers' encouragement of children's use of certain ways of using language leads to better learning and conceptual understanding (see Mercer and Littleton, 2007).

Concluding Remarks

There is certainly much more to discover about the ways that language experience in the classroom can contribute to the development of children's abilities to communicate, learn, and reason, but what is known now provides a well-informed basis for the creation of a more dialogic, and more effective, educational practice. It is an uncontroversial claim that through social interaction, children learn how language can be used to describe the world, to make sense of life's experience, and to get things done. However, what children learn from talk in the classroom, and how significant it is for their psychological development and educational progress, will depend a great deal on the range and quality of the dialogs in which they engage.

Acknowledgment

The author wishes to thank Neil Mercer for his comments on an earlier draft and for his permission to draw upon material in their book (*Dialogue and Development*) in the preparation of this article.

Glossary

Centrality – Refers to the number of ties one has to others in a network. Those with more ties may have more access to resources contained within the network.

Closure – Refers to the interconnections members have with one another, that is, the social ties among the network members that are historical and bridging.

Density – Refers to the number and strength of ties among individuals within a social network. In formal network theory, density refers to the number of ties observed divided by the number of total possible ties in a bounded group.

Homogeneity – Being in a group with similar demographic and other characteristics.

Homophily – The concept that friendships tend to form among people who perceive themselves as similar to one another.

Proximity – A basis of interpersonal attraction characterized by physical or psychological proximity to another.

Social networks – The social ties among a group of individuals, which can involve as small as two “also known as a dyad” or much larger numbers of individuals.

The social networks of children and youth are formed in the context of their families, peer groups, schools, and neighborhood communities. Researchers studying social networks of children and adolescents have primarily been interested in the formation of friendship relations and the impact of social location on academic achievement and social development. Social networks are commonly defined as the social ties among a group of individuals, which can involve as small as two – also known as a dyad – or much larger numbers of individuals. Through these social ties, social norms can form which constitute social capital, the resources within social groups that increase the potential for members to achieve their interests and goals (Coleman, 1990). Scholars have identified several characteristics of social capital that have direct implications for the formation and function of social networks. These properties include density, closure, and trustworthiness (Coleman, 1988).

Density generally refers to the number and strength of ties among individuals within a social network. In formal network theory, density refers to the number of ties observed divided by the number of total possible ties in a bounded group. The degree to which multiple network members share reciprocal ties with one another determines the cohesiveness of the network (Wasserman and Faust, 1994). Dense social networks can have positive or negative influences on their members depending on the social context of the network and its goals. In children's social networks where academic performance is valued and children have strong relationships with each other, these values are likely to be transmitted and upheld by the network. However, in situations where networks are dense and the goals are negative, such dense ties can encourage negative behavior patterns. For example, Haynie (2001), examining friendship networks using Add Health data, finds a general association with an adolescent's delinquency and that of his or her friends. Results indicate that network density appears to be a critical component of the delinquency–peer association.

Closure refers to the interconnections members have with one another, that is, the social ties among the network members that are historical and bridging in multiple contexts. In formal network theory, closure refers to how all of an ego's alters (e.g., a student's teacher, parent, and sibling) communicate, thereby closing the circle. Coleman (1990) argues that intergenerational social closure, the reciprocal social ties that connect children with their families, help to create functional communities where educational goals are strengthened and acted upon. Parent social networks that include the parents of their children's friends can build social capital that is reinforced through their children's peer networks, their own adult networks, and the intergenerational family and community networks that the parents and their children share. This point is illustrated by Offer and Schneider (2007), who show in their analysis of data from a study of parents and children in 500 families that adolescents' friendships with peers generate friendships among the parents of their friends, suggesting that information and social resources flow from children to adults as well as from adults to children.

Bridging social networks can be especially beneficial for members in low-resource networks. Distinguishing between weak and strong social ties, Granovetter (1973) finds in his study of job searches how individuals in

low-resource networks learn about employment opportunities through weak ties outside their immediate social circle. A similar argument has been made by Kim and Schneider (2005) with respect to schools, where they show how immigrant parents who broker and maintain ties to individuals outside their school communities gain access to more resources for their children's education.

Dense social networks with high degrees of closure promote trustworthiness (Coleman, 1988). This concept of trust has been further developed by Bryk and Schneider (2002) in their study of the effectiveness of urban school reform in Chicago elementary schools, where they show that relational trust which is formed through shared expectations and fulfillment of mutual obligations increases the likelihood of school change and higher academic performance. When relational trust is strengthened in social networks among various role sets, including teachers and parents, teachers and students, and parents and administrators, and the academic and social welfare of the students becomes the top priority, such relationships create a more productive learning environment for the entire school community.

The Study of Social Networks

The social networks perspective distinguishes itself from other research approaches through its emphasis on the importance of the relationships between units in a study. In contrast to many non-network research studies, studies of social networks begin with the assumption that individuals and their actions are interdependent, that is, the behaviors and/or actions of one individual influence the behaviors and/or actions of others within a group. Social network analysis also understands the relational ties which exist between individuals within a network to be pathways, which enable the flow of resources among members. From the perspective of individuals within a group, network analyses also endeavor to ascertain how network structure facilitates or constrains individual action in a network (Wasserman and Faust, 1994).

The study of social networks could be understood as focused on two distinct methodologies: (1) formal network analysis and (2) observational network analysis. Formal network methodology employs mathematical models to describe the relationships within a specific, bounded population. To obtain this information, researchers first identify all members of the population of interest and then ask each subject to report on his/her relations with every other member of the group. In this instance, researchers try to obtain information from all members of a fully enumerated social group, which is often called complete network data (Marsden, 1990).

The methods of describing network structure are being modified and tested; now researchers can examine small

and large networks, with ten to hundreds of thousands of nodes sites of network connections (Moody, 2001a; Wasserman and Faust, 1994). Technological advances over the past 50 years have enhanced the development of these models from those that were static to ones that are more fluid. New techniques, such as dynamic network visualization, capture motion and change within networks, allowing researchers to study how networks develop and change through static flip books and/or dynamic movies (Moody *et al.*, 2005). These new methods are designed to visualize relational change beyond more conventional techniques that use one- or two-dimensional pictures with points, lines, and arrows showing directionality.

Egocentric network studies also use formal methodology to focus on how networks operate around individuals. In these studies, subjects typically report affiliations and ties through surveys or structured interviews. Although these data tend to be less comprehensive than that of the complete network in which they are embedded, they are generally useful in studies where the research question concerns how individuals and small groups evaluate their position and affiliations (e.g., centrality – one who has ties to most network members; popularity – more friendship nominations than one would expect based on network composition) in relation to others in the network. Studies of this type generally generate data through peer nominations where subjects are asked to name their three closest friends. These questions have been asked in the major national longitudinal studies conducted by the National Center of Education Statistics (NCES) over the past 40 years beginning with *High School and Beyond*, followed by the *National Educational Longitudinal Study of 1988 (NELS: 88)*, and, more recently, in the *Educational Longitudinal Survey of 2002 (ELS: 2002)*.

Observation field-based studies provide extensive descriptive information on how members of a group interact with one another in multiple situations, often over time. One of the most recent examples of this type of study was conducted by McFarland (2001) where he used student and teacher surveys, interviews, and school records to examine how social networks contribute to active resistance in 36 classrooms in two Midwestern high schools. Measuring individual and clique-level status, density, and academic standing, McFarland comprehensively describes the characteristics and processes by which student networks create opportunities for student resistance to instructional activities, showing that resistance is related to the structure of student relations and not simply a result of individual responses to teachers' instruction.

Social Networks and Young Children

Friendships among children are generally understood to be significant in determining future developmental outcomes.

The friendships that children form with one another are resources that they can draw upon to cope with the psychological and social stresses of developmental transitions, such as that from childhood to adolescence. In understanding how development is impacted by childhood friendships, Hartup (1996) maintains that it is not enough to know that a child has friends; we should also know something about the identities – including attitudes and behavioral characteristics – of that child's friends, as well as the nature of their relationship. In other words, more comprehensive assessments of children's friendships are needed in order to bring more predictive power to bear on anticipating a child's future disposition and social competence.

Given the salience of friendship networks in the study of child development, it is not surprising that many studies of social networks among children have focused on the formation of peer groups. One of the most frequently cited studies was conducted by Hallinan and Tuma (1978), where they examined the friendship networks of fourth, fifth, and sixth graders over time. Asking children to name their best friends, friends, and nonfriends over time, the researchers measured friendship stability formed through personal relationships and those that were formed through learning-related tasks directed by the teacher. Contrary to expectations, they found that within-classroom student network groupings that were determined by the children's choices, best nominated friends did not emerge as more stable than those friendships that developed through teacher-assigned groups. Their findings suggest that teacher grouping based on classroom tasks strongly affected children's friendship formations.

More recent studies of social networks have also pursued the influence of teacher instructional practices on children's friendship choices. Plank (2000) examined how teachers' task and reward structures influence the academic and social hierarchy in the social networks of Hmong and white students in ten classrooms in five Midwestern elementary schools. Focusing on the effects of social hierarchy on racial and ethnic integration, he found that students from higher social classes tended to be at the center of classroom social networks. Plank suggests that norm-based task and reward structures seem to produce social groups that align across class and racial lines, concluding that the pedagogical style of the teacher directly influences the social network structure of children in the classroom.

Another study by Kubitschek and Hallinan (1998) also focused on teacher activities and friendship patterns. Using social network data, they establish a link between teacher-tracking practices and student friendship choices, demonstrating that these linkages cohere around three bases of interpersonal attraction: propinquity, similarity, and status. They argue that the nature and effects of tracking practices determine friendship choices due to their propensity to encourage intra-track communication

(propinquity), to create greater similarity among students within tracks (similarity), as well as to reflect stratification trends in greater society (status).

Cairns *et al.* (1995) sought to examine the relative stability of friendships and social networks in childhood and adolescence among 131 fourth- and seventh-grade students in two suburban schools over a 3-week period. The researchers used respondent interviews administered at the beginning and end of the observational period to determine social group membership through the social-cognitive map (SCM) procedure. For both children and early adolescents in this study, Cairns *et al.* demonstrate that friendships and social group membership are generally more fluid than has previously been recognized. This fluidity of friendship ties has also been found in adolescent peer and friendship ties, with youth repositioning their social ties throughout the high school experience (Steinberg *et al.*, 1996). However, friendships developed through school-sponsored activities appear to be more stable (Schneider and Stevenson, 1999).

Social Networks and Adolescents

Just as peer interactions play an important role in the development of young children, so also are peer groups influential in adolescent identity development. Adolescence marks the time when young people seek to establish an independent identity from their families and seek acceptance and a sense of belonging through peer groups. As this occurs, similar shifts in the locus of peer relations occur, from dyadic or small-group relationships to peer groups or crowds (Brown and Lohr, 1987). The importance of crowd affiliation on identity development was studied early on by Brown *et al.* (1986). Based on subjective responses of adolescents regarding the importance of crowd affiliation and why it was important, the researchers found that importance of crowd affiliation was negatively associated with age. Thus, younger adolescents tended to value crowd associations, while older adolescents relied on them less heavily, due to the strength of established friendship networks. Furthermore, respondents' sense of identity was not related to the importance they placed on crowd affiliation, but was related to the centrality of their position in the peer network.

Crowd affiliations have also been demonstrated to predict future behaviors, educational attainment, and general psychological adjustment in adolescents. Using widely recognized identity categories such as the jocks, brains, and the princesses, Barber *et al.* (2001) found that jocks and brains had the most positive adjustment in later years, primarily due to their involvement in school-related activities in tenth grade. Future adolescent adjustment was also found by Fuligni *et al.* (2001) to be related to adolescent peer

dependence. The more adolescents reported being willing to sacrifice their talents and school performance for being in a particular group, the poorer was their academic performance and overall adjustment. Taken together, these findings suggest that peer-group orientation plays an influential role in adolescent's identity development.

Due to its relationship to peer groups, identity development in adolescence has been a topic of particular interest to social network researchers. Collecting data on nearly 6000 high school students in California, McFarland and Pals (2005) explore how social networks affect the identity development of adolescents. They found that, while category memberships are highly influential in identity development, the network characteristics of prominence, homogeneity, and bridging lead to higher salience of identity imbalance, which in turn leads to an increased incidence of identity change. Homogeneity, that is, being in a group with similar demographic and other characteristics, exerted the greatest influence on identity change, revealing that, over time, social conformity inhibits identity instability and inconsistency.

The concept that friendships tend to form among people who perceive themselves as similar to one another is termed homophily. These social affiliations tend to be aligned around traits on which people share values (value homophily) or social status (status homophily). McPherson *et al.* (2001), in their review of homophily, argue that the most persistent traits which determine network homogeneity are race and race-like ethnicity.

The tendency toward network homophily and homogeneity is evidenced in several studies. Jackson *et al.* (2006), in their study of 1268 fifth graders' peer and teacher nominations of classroom social network relationships, asked students to rate who is most like them (Like Most), most not like them (Like Least), a leader (Leader), and who is aggressive (Fights). They found that classroom racial composition and the race of the teacher are directly related to the nominations of students into each of these groups. In classes that are majority white, black students are significantly less likely to be nominated by both peers and teachers as a leader, more likely to be categorized as aggressive, and less likely to be nominated in friendship networks. However, they also demonstrate that, as black students are increasingly represented in the classroom, black children's nominations to these categories also improve. Based on these findings, the researchers conclude that white children tend to be more protected in majority black environments – a phenomenon they attribute to their status in the broader social community and to the history of discrimination and bias against blacks.

Examining the substantive integration of friendship networks in varied school contexts, Moody (2001b), using data from the Add Health Study, draws on contact theory to explore the relationship between friendship segregation and school organization and diversity. His findings suggest

a curvilinear relationship between heterogeneity and friendship segregation, finding that once a particular threshold of race salience is reached in the school, integration peaks and then falls. Moody maintains that schools have the greatest effect on racial friendships when they can structure racial mixing through the racial integration of extracurricular activities.

Virtual networks have emerged as sites for establishing socialities, although early studies suggested that ties created through the Internet were weak. Today, adolescents and young adults frequent sites such as MySpace, Facebook, and online dating websites to form new relationships. The relationships formed within these groups may or may not exist additionally outside of virtual space, but they are nonetheless real, to varying degrees. Youth participate in these networks for generally similar purposes as their traditional social groups: to forge new social relationships, find and interact with people who share their interests, and find people to date. Online relationships are now considered a part of the social world of most adolescents. These relationships are becoming increasingly significant to research on social networks not only because they are more prevalent, but also because they refine and reshape understanding of the motivations underlying adolescent friendship formation as well as the possible avenues in which those relationships can be forged. In other words, adolescents who may have traditionally been understood as social isolates, due to their difficulties forming interpersonal relationships with face-to-face friends, now have other outlets for forming relationships which need to be brought to bear for understandings of peer networks in schools.

Previous research into adolescent friendship formation has primarily been analyzed through social needs and social compensation perspectives. The social needs perspective attributes the motivations behind adolescent development to personal needs for intimacy, self-validation, and companionship, whereas the social compensation perspective focuses more on the relationships that adolescents have with their parents to understand motivations behind friendship formation. Research supporting the social compensation approach is exemplified in the findings of Mesch and Talmud (2006). In a survey of a nationally representative sample of adolescent households in Israel (1000 in total), this study examined differences between adolescents who formed online friendships from those who did not, as well as adolescents' perceived strength of social ties in terms of the nature of initial contact (either online or face-to-face). The study found that adolescents reporting conflicts with parents turned to online friendships rather than face-to-face relationships, in part due to the anonymity of online communication. Further, this study's findings challenge previous research of the strength of social ties in online relationships, asserting that it is not technology which affects friendship formation, but rather the social embeddedness of the ties.

Social Networks, Educational Expectations, and Academic Performance

Social networks in schools have been demonstrated to significantly affect students' academic performance. Friendship ties with academically oriented peers have been found to produce academic advantages, particularly for youth in low-performing schools, suggesting that youth in a social environment with lower resources can be protected by the social capital generated in their academically oriented peer relationships (Crosnoe *et al.*, 2003). Further, in a study of friendship networks among 929 fifth-through seventh-grade children, Altermatt and Pomerantz (2005) found that respondents' grades were highly predicted by their friends' report card grades for that academic year – a positive educational achievement effect of their social networks. Nesting their findings within social comparison theory, the authors conclude that friendships with high-achieving peers benefit both high achievers and low achievers. They find moderate evidence however that low achievers' self-esteem decreases as result of friendships with peers who outperform them academically.

In several studies, hierarchy and clique development among students within classrooms have been linked to homogeneity of academic achievement and academic track placement. In a longitudinal study of 1477 pre-adolescents from fourth through seventh grade, Hallinan and Smith (1989) found that classrooms with low degrees of academic variance – especially with regard to high-ability students – also tend to have a low incidence of social clique formation. This finding suggests that academic tracking may have negative consequences for student social development, especially among gifted students. However, in classrooms with mixed-ability students in which the teacher stressed the importance of high academic achievement, the researchers found that cliques tended to form around homogeneity of achievement. This particular finding suggests that teachers – especially those with mixed-ability classes – should be mindful of how they organize their classroom with regard to maximizing academic achievement for all students.

Fuligni *et al.* (1995) maintain that the selection of adolescents into academic tracks should be seen as an important environmental change with impacts on their developmental transition from childhood to adulthood. Measuring adolescent's math grouping status over time in sixth, seventh, and tenth grade, they find that middle- and upper-level students benefit in both their math-related self-concept and academic performance; for low-ability-level students however, their self-concept initially increases, but decreases by tenth grade. Thus, low-ability grouped peers emerge with lower self-concepts than their nontracked peers.

Examples of studies which combine academic data with social network data serve as significant contributions to the study of how networks affect academic outcomes in

children and youth. Supplementing academic information in the Add Health study, the Academic Achievement supplement to Add Health (AHAA) facilitates the measurement of the effect of social networks on academic achievement, controlling for different family, school, and classroom contexts. Early research using this data has found strong relationships between peer networks and advanced mathematics course taking, a factor that weighs considerably in youth's academic careers (McFarland, 2006). A similar study using this data set also shows that female friendships boost advanced mathematics course taking and counter the traditional drop-off in female adolescent participation in advanced math and sciences (Riegle-Crumb *et al.*, 2006).

Social networks need not involve students to promote student performance. Morgan and Sørensen (1999) argue that intergenerational social closure – in this case, dense network connections between the parents of students – has both the potential for negative as well as positive effects on academic achievement, depending on the resources available within the community. They suggest that horizon-expanding schools and organizations shift the roles of monitoring norms and disseminating expectations away from the network actors and toward professionals and others outside of the primary network. Using parent and student-level data from the National Educational Longitudinal Study of 1988, the authors compare math test score gains in horizon-expanding schools and norm-enforcing schools, finding that horizon-expanding network configurations produce greater academic benefits than do norm-enforcing schools in the public school context.

Furthermore, social trust generated within school institutions has been found to generate greater efficiency and effectiveness in educational interventions, with teachers as members activating capital transferred from administrators, reform experts, and/or other peers. Similar to the concept of functional specificity, Frank *et al.* (2004) find that taxing or diffusing social capital reduces its effectiveness. In other words, the less pressures administrators place on their teachers at one time, the more efficiently they are able to tap available resources in the service of implementing educational innovations of benefit to their students.

Social Networks, Deviant Behaviors, and Health

The influence of peer groups on children and youth's development yields both positive and negative outcomes. Peer networks have been demonstrated to promote prosocial behaviors, such as extracurricular participation and leadership (Brown, 1990; Elder, Jr. and Conger, 2000). However, peer groups can also contribute to negative outcomes for youth, such as increased participation in

antisocial behaviors, often to the detriment of their educational futures. Studies examining the operation of delinquent behavior among adolescent peer groups have found significant network effects – in particular, characteristic differences between antisocial and prosocial peer networks (Giordano *et al.*, 1986). In a study of how the peer networks of aggressive children function to promote bullying and other deviant behaviors, Cairns *et al.* (1988) examined the role of aggressive children within their social networks in school, investigating how network structure relates to antisocial behavior. Using cluster analyses and best-friend nominations, they find that aggressive youth do not differ from control subjects in the degree of social cluster membership – in fact, many are often solid, central members of peer groups. These findings demonstrate that aggressive youth are not more likely than other students to become social isolates, and do have networks of peer support, despite being disliked for their behavior.

The development of increasingly sophisticated sociometric data has enabled researchers to examine the etiology of peer socialization into behavior norms, such as the process by which socially isolated youth are initialized into gangs and commit crimes against property. In analyzing these particular delinquent behaviors, Kreager (2004), using Add Health data to identify social isolates, found that isolation alone does not predict future delinquency, which replicates the findings of previous studies (see Haynie, 2001). However, when isolation is combined with peer conflict, or otherwise negative peer encounters, significant increases in delinquency and delinquent peer associations were measured.

In a related study, van Lier *et al.* (2005) support the significance of peer rejection as a predictor of deviance in their study of antisocial behavior among French-Canadian and Dutch boys and girls. Using peer nominations to classify antisocial behavior developmentally from childhood to early adolescence, the researchers employ a network analysis and find that peer rejection most greatly correlates with antisocial behavior and occurs more readily in youth involved in high-delinquency behavior patterns. This suggests that the process by which homophily occurs is a consequence of pre-existing preferences rather than a result of the socializing norms of the peer group.

Additionally, health-related behaviors of youth have been closely linked to social network affiliations. Early substance use has been tied to social networks, in particular, adolescent drug use (Kandel, 1978), drinking (Stattin *et al.*, 1989), and cigarette smoking (Alexander *et al.*, 2001). Moreover, early and risky sexual behavior has been linked with peer-group membership (Bearman *et al.*, 2004). Advances in social network theory and design offer increasingly rigorous and nuanced evidence of how children's behavior and educational futures are affected by the social networks in which they are embedded.

Sociocultural Issues in Motivation

R A Walker, University of Sydney, Sydney, NSW, Australia

Introduction

Until recently, motivation has been considered to be an individual phenomenon. Motivational theorists have conceptualized key constructs in individualistic terms and emphasized the individual origins and nature of motivation, although they have also long recognized that contextual or social factors have a significant influence on these individual processes. Recently, theorists have suggested, after Vygotsky, that motivation is social in nature. Sivan (1986) first suggested this idea 20 years ago but it received a major impetus with the publication of an article by Hickey (1997) 11 years later. Since then, interest in the social nature of motivation has grown as a small number of book chapters and journal articles have been published, and conference papers have been presented on the topic. Although some motivational theorists (Winne, 2004) remain skeptical of this theoretical development, this article suggests that this perspective is worthy of consideration.

Although Vygotsky considered that intellectual and affective aspects of learning were interdependent, his own work foregrounded the intellectual aspects of learning. Sivan's (1986) seminal article provided the first sociocultural analysis of motivation and was based on conventional Vygotskian notions, such as the zone of proximal development (ZPD), assisted learning, peer learning, internalization, and intersubjectivity. Hickey's (1997) article, on the other hand, was primarily concerned with examining conventional motivation research in relation to instructional and educational reform practices derived from Vygotskian sociocultural ideas. Hickey's (1997) article coincided with a renewed interest in the situated and contextual nature of motivation and these ideas have tended to be seen as synonymous with sociocultural theory. While concern with context is a legitimate aspect of Vygotskian sociocultural theory, it is not the defining aspect of such a perspective. The key commitment of sociocultural motivational theorists is their recognition of the social nature and origins of motivation. Accordingly, sociocultural researchers attempt to explain how motivational goals, values, standards, and interests are socially constructed, and how they emerge and develop from social interactions and are manifested in collaborative and individual action.

As Walker *et al.* (2004) have pointed out, sociocultural theorists of motivation require reconceptualization of motivational concepts in social terms. With only a relatively small number of exceptions however, most motivational researchers (e.g., Perry *et al.*, 2006) have maintained

their commitment to motivation as an individual phenomenon while acknowledging the role of social factors, or context, as influences on motivation. To differentiate these theorists and researchers from sociocultural motivation researchers, Walker *et al.* (2004) have referred to them as social influence theorists, applying to the motivational domain a distinction that Rogoff (1998) made in the domain of learning and thinking. This distinction has been used in the current article to frame a discussion of theoretical and meta-theoretical issues and as a basis for selection of empirical research discussed in the article.

Sociocultural Theories of Motivation

The understanding of motivation as social in nature involves complex issues concerning the relationship between the social world and the world of the individual. Sociocultural theories endorse a social epistemology and accord analytical or theoretical primacy to the social world over the individual world, while recognizing that these worlds are closely interlinked and interdependent. According primacy to the social origins of motivation does not, however, mean that explanations of individual motivation can be reduced to social explanations or that social processes determine individual motivation. Sociocultural reductionism (Martin, 2006) and social determinism are avoided in sociocultural theories of motivation through theoretical notions which explain how the social world is internalized and externalized by individuals, and which assert that while there is a dynamic interdependence between the social and individual worlds, they are distinguishable and qualitatively different from each other. Valsiner (1997) has called this latter idea inclusive separation and uses it to explain how bidirectional exchanges occur between the social and individual worlds. Bidirectional exchanges are also explained through Vygotskian concepts such as the ZPD and the notions of transformative internalization and externalization. Transformative internalization and externalization explain how aspects of the social world are selectively internalized by the individual and then externalized in subsequent social interactions; these processes, as explained below, are active and transformative so that the social world is not imprinted on, or transmitted, to the individual, and the individual, in turn, has a unique impact on the social world through transformative externalizations. Taken together, these sociocultural theoretical ideas avoid the reduction of

personal phenomena to social interaction or social processes at large and recognize the agency of the individual. They explain how individual motivation can have social origins yet the individual's intrapsychological motivational functioning is still relatively autonomous from the social world.

These meta-theoretical notions have been endorsed in the work of some, but not all, sociocultural motivation theorists (Walker, 2006; Walker *et al.*, 2004; Pressick-Kilborn *et al.*, 2005). Hickey (2003) asserts that the social world, or context, and the individual are tightly bound or fused with each other, and appears to suggest that they are not distinguishable. This view raises important issues and problems concerning the motivational agency of the individual and the reductionist position of the individual in relation to the social world. Similarly, the common categorization (Hickey, 2003) of the sociocultural motivation worldview as contextualist is inadequate as it makes context the theoretical focus rather than the social origins of motivation.

Sociocultural motivation theorization has mostly focused on well-known and central aspects of Vygotsky's writing: culture and cultural practices, the ZPD, transformative internalization and externalization, and interpersonal relations and intersubjectivity. Taken together, these sociocultural ideas contribute to an explanation of the way that motivation, conceptualized as social in nature, is internalized to become an individual process. Although there is general agreement among sociocultural motivation theorists (e.g., Sivan, 1986; McCaslin, 2004; Walker *et al.*, 2004) on this view, it is not accepted by Hickey and Granade (2004) who consider that the goals and values that support and motivate learners to engage "reside in the practices of knowledgeable communities rather than the hearts and minds of individuals" (p. 224). Theorists such as Walker and associates (Walker, 2006; Walker *et al.*, 2004; Pressick-Kilborn and Walker, 2002), on the other hand, consider that while academic practices have motivational properties, motivation is an internalized attribute of human beings. For instance, aspects of the academic practices of reading and writing may be motivating to learners, but the motivation to engage in these practices is internalized as learners work collaboratively on these activities.

Culture and Cultural Practices

Culture and cultural practices are considered, from a sociocultural perspective, to play a critical role in the construction and emergence of motivation. Cultural practices (Miller and Goodnow, 1995) are recurrent actions or activities that may be maintained, changed, or challenged. They are valued by the communities that engage in them and are associated with a sense of belonging or identity and with particular forms of discourse. They help to

structure learning and thinking activities and have motivational and affective properties and consequences. The academic practices of the school and the classroom, such as those associated with reading and writing for instance, are one type of valued cultural practice. Sociocultural theorists (Walker, 2006; Walker *et al.*, 2004; Nolen, 2001, 2007) consider that motivation is socially constructed as learners engage in academic practices, and so can be considered to emerge from these practices. Sivan (1986) has presented classroom motivation as a socially constructed norm, which, like other classroom norms, forms the basis on which both teacher and student expectations and judgments are made. These expectations include how motivation is displayed in the classroom in the form of motivated behavior that demonstrates interest and willingness to engage in learning activities.

Zone of Proximal Development

The ZPD refers to the learner's ability to successfully complete tasks with the assistance of more capable other people, and for this reason it is often discussed in relation to assisted or scaffolded learning. The creation of ZPDs involves assistance with the cognitive structuring of learning tasks and sensitivity to the learner's current capabilities. Sociocultural (e.g., Sivan, 1986) and mainstream motivational theorists (e.g., Brophy, 1999) have observed that these aspects of the ZPD make it an inherently motivational zone; the ZPD is optimally challenging (Sivan, 1986) because tasks are calibrated to the learner's level, while appropriate support and scaffolding ensure that tasks can be completed successfully. Assistance from others also helps the learner to learn how to work on difficult tasks and how to control or manage anxiety and frustration in the process. Additionally, working within the ZPD is inherently motivating because it involves the transfer of responsibility, or control, for learning, from the teacher or more capable other to the learner. This transfer of control is motivating for the student as it acknowledges student mastery of the task, and hence the learner's developing efficacy. Interaction within the ZPD is also likely to lead to the recruitment of the learner's interest in the task or knowledge domain as the learner comes to value and appreciate the knowledge which is valued by a respected, more capable other person. Furthermore, as learners come to achieve mastery in a knowledge domain, they are more likely to appreciate the relevance and value of the knowledge domain.

The ZPD can also be considered to be a relational (Goldstein, 1999) or affective zone. Goldstein (1999) has characterized the ZPD as a socially mediated space that is formed through relationships involving sensitivity and trust. In a classroom, this space is created by the interactions between students and between students and their teacher, as they engage in supportive activities that

develop learner confidence and positive emotions. This consideration of the ZPD as a shared affective zone also has important motivational implications; the emotional quality and tone of interaction in the ZPD and the sense of caring engendered can have important implications for students' engagement in learning and willingness to challenge themselves.

The ZPD has been extended by Valsiner (1997) into a system of zones which recognizes not only the importance of assisted learning, but also the factors which may assist or constrain learning, and, as Pressick-Kilborn and Walker (2002) have suggested, motivation. Valsiner's system of zones has been used by Pressick-Kilborn and Walker (2002) to understand the development of interest in a classroom learning community.

Transformative Internalization and Externalization

The reciprocal notions of transformative internalization and externalization play a central role in many, but not all, sociocultural theories because they explain the processes through which aspects of the social world become a part of the world of the learner, and conversely how the learner's actions and behavior impact upon his/her social world. Viewed from the perspective of motivation in the classroom, the process of internalization refers to the way individuals selectively internalize values and standards from their interactions with others in the ZPD as they engage in the academic practices of the classroom. The process of internalization is active, constructive, and transformative (Walker *et al.*, 2004) so that the goals, values, and standards constructed by the learner cannot be considered to be transmitted by others. Rather, goals, standards, and values are actively modified or changed by the learner in the process of internalization. When standards and values have been internalized by a learner, they are subsequently externalized in the form of motivated action, behavior, and language, so that internalization may be inferred from these expressions of classroom engagement. It is important to recognize, however, that externalization is also an active and transformative process, so that standards and values are transformed as learners externalize them through their interaction with peers and others.

While the notion of internalization has been prominent in the work of sociocultural motivation theorists, transformative externalization and its relevance for understanding motivation and engagement have so far only been raised in the work of Walker and associates (Walker *et al.*, 2004; Pressick-Kilborn *et al.*, 2005). Walker and associates have identified the role that transformative externalization plays in motivated action and explained how this impacts on the social world. While most theorists (e.g., Sivan, 1986; McCaslin, 2004; Walker *et al.*, 2004)

consider internalization to play an important role in motivation and engagement, Hickey has argued that it is of little importance (Hickey, 2003; Hickey and Granade, 2004). In part, Hickey's assertion is based on a lack of recognition of the transformative nature of internalization, but, in part, it is based on the view that goals, standards, and values are tightly bound to the context in which they are constructed, thus making internalization irrelevant to the understanding of motivation. This view is problematic in that it does not recognize that these goals, standards, and values may become personal attributes that motivate engagement in other contexts.

Interpersonal Relations, Intersubjectivity, and Co-Regulation

The nature and quality of interpersonal relationships between students and their teachers and peers are therefore important in sociocultural perspectives on motivation as they influence the internalization and externalization of motivational standards and values. Interpersonal relations and intersubjectivity are also important for understanding the way that learners and their peers regulate each other's activities, and their motivated engagement in those activities. The notion of co-regulation has been developed in the work of McCaslin *et al.* (2004) and refers to the regulation that teachers provide students and that students provide for each other as they work on activities in the ZPD.

Sociocultural Research in Motivation

With the exception of McCaslin's work, only a small number of sociocultural motivation studies have been conducted to date. These studies have been conducted in different motivational domains and while they have adopted differing sociocultural theoretical positions, they all have a commitment to investigating the social nature of motivation. While some of the studies are developed from an explicit Vygotskian theoretical framework (McCaslin, 2004; Pressick-Kilborn and Walker, 2002), others (Nolen, 2001, 2007; Middleton and Perks, in review) do not ground their research in this framework. Most of the studies have been conducted in naturalistic classroom contexts.

McCaslin outlined a number of research projects undertaken over a 20-year period from the mid-1980s to the early 2000s, all of which were based on sociocultural ideas, particularly those related to the ZPD and internalization (McCaslin and Hickey, 2001; McCaslin, 2004). The projects focused on interpersonal relationships at home and in school and were developed from a model of co-regulation which was considered to facilitate the internalization of social supports and promote adaptive

learning. Co-regulation involves the joint control of an activity by all participants involved in the activity and is enacted by negotiation between the participants. Adaptive learning (McCaslin, 2004) was defined as involving “the internalization of goals, the motivation to commit, challenge, or reform them; and the competence to enact and evaluate those commitments” (p. 254). As such, adaptive learning research examined the opportunities various home and school environments and tasks allowed for the integration of both affective and intellectual aspects of learning. An important recognition in these projects was the understanding that co-regulation in the ZPD does not always enhance motivation and learning and may actually impede it. That is, while co-regulation may have benefits for learners, sometimes learners influence and regulate each other in ways that lead to diminished learning outcomes and reduced motivation. Taken together, McCaslin’s (2004) projects illustrate the potential of Vygotskian sociocultural ideas for understanding the following aspects of student motivation: “(1) the function of task opportunity and the enactment of self-directed activity and motivational beliefs, (2) the affordances of teacher classroom management for student-learning cultural rules of responsibility and citizenship (3) the influence of parent beliefs and behaviour on children’s emergent identity and the negotiation of personal commitments at school, and (4) the power of peer participation in student-valuing curriculum tasks, learning motivation, and motivation to learn” (p. 250). McCaslin’s (2004) research demonstrates the relevance of Vygotskian sociocultural ideas for understanding the social nature of motivation while also recognizing the place of the individual within the sociocultural realm.

Pressick-Kilborn and Walker (2002) reported an investigation into the emergence and development of interest in a primary school classroom. In the study, interest was conceptualized as emerging from collaborative activities in a fifth-grade science community of learners. This conceptualization emphasized the dynamic and interdependent relationship between the children and their classroom activities for understanding the development of interest and suggested that traditional distinctions between situational and personal interest were problematic. Studying interest in a real and complex classroom setting presented challenges to distinguishing situational and individual interest along traditional lines. While, in some activities, students participated in ways that indicated an ongoing and more personally meaningful form of interest in learning, the situational aspect of interest was always apparent. Features of tasks, such as their hands-on or collaborative nature, contributed to personal experiences of interest in learning in the context of a real classroom. The analysis of the development of interest in the study drew on the integration of several established sociocultural notions: the idea of a community of learners, the ZPD and its extensions (Valsiner, 1997), and Valsiner’s

(1997) notions of canalization and self-canalization. Canalization refers to the way that cultural practices channel the activities of individuals, while self-canalization refers to the way individuals are able to channel and direct their own activities. The canalization of opportunities in the social world thus creates the context in which values and goals are internalized and from which interest may subsequently emerge. It is important to recognize, however, that individuals may resist these canalization processes.

The investigation extended over a period of 6 months and involved ethnographic observations in the classroom community, and student and teacher interviews. Students also created personal-interest trajectories to indicate their perceived levels of interest in specific science-based activities during classroom lessons and over the duration of the study. These trajectories allowed insights into changing patterns of interest both at the individual and class level. Pressick-Kilborn and Walker (2002) developed individual case studies from their research data and used them to show how the classroom community both promoted and constrained the emergence and development of interest. The case studies illustrated not only how classroom science practices canalize interest development, but also how processes of self-canalization may lead students to resist engagement in these activities, and thus limit their interest development.

Nolen (2001, 2007) investigated, in a longitudinal study, children’s emergent motivation to read and write and its relation to their developing sense of the nature of reading and writing. The study investigated teachers and their students across a 4-year period, from kindergarten to the end of third grade, during which time they were observed in class activities and interviewed annually about reading and writing. The study examined teachers’ goals in literacy instruction and the literacy activities that students engaged in, and drew relationships between these activities, the students’ understanding of the nature and purpose of literacy, and their motivation to engage in literate activities. A particular focus of the research was the way in which teachers and students jointly constructed their literacy activities and, where such opportunities were limited, how students collaboratively reconstructed the literacy activities they were required to engage in.

The first year of the study involving kindergarten teachers and their students was reported by Nolen (2001), although the focus of this publication was on a subset of students who were at risk for reading and writing difficulties. Classroom observations showed that while all of the teachers engaged in common literacy activities, they differed considerably in the variety and amount of time spent in various literacy activities. Teachers differed in the extent to which they gave students the opportunity to read and write connected text, to choose their own subject matter and activities, and in how structured classroom activities were. The teachers

also differed in the extent to which they emphasized the motivation for learning to read and write, skill development, small and large group instruction, multiple task structures, and autonomous student work. Student interviews showed how student understanding of the nature and purpose of literacy is related to commonly employed literacy activities, and how literacy practices and activities are related to student engagement in and liking of those activities.

The remaining 3 years of the study, from grades 1 to 3, were reported by Nolen (2007) and demonstrated that as the social meaning of literate activity was co-constructed in classroom communities, specific motivations emerged in relation to reading and writing. As with the earlier study, the most frequent and valued activities in classrooms had the greatest impact on students' perceptions of themselves as readers and writers. Where the emphasis, for instance, was on writing for self-expression and for authentic reasons (an author's tea involving family and friends) students were developing identities as writers. Some instructional activities also provided opportunities for choice and autonomy while others were more controlling and allowed little room for independent learning. Student motivations, such as interest, enjoyment, mastery, and ego concerns, emerged from these differing instructional contexts and activities. Their motivations and actions were also shown to be related to the students' differing developmental skill trajectories.

Middleton and Perks (in review) present a view of mastery goal motivation as socially constructed through the written dialogic interactions of students with their teacher in a writing course. The study examined the writing and motivational goals of 17 students enrolled in an elective creative writing class in a rural high school in the United States. A writing workshop approach in the class involved students in extended periods of writing as well as regular conferencing with their teacher. The students were also required to keep dialog folders which contained samples of their writing and a written dialog addressed to their teacher concerning their writing and how it was progressing. They were also asked to identify kinds of feedback that would support them in their writing. The teacher collected these folders at the end of every lesson and responded in writing to each of the students. These dialog folders, many over 30 pages in length, were subjected to a layered discourse analysis which focused on the situated identities of the students, the discourses they engaged when writing, the terminology and language used, and the cultural models enacted by the students and teacher. The dialog folders were also analyzed for the enactment of mastery goals.

The findings of the discourse analysis were developed into a model of mastery engagement in the writing domain. The model suggests that students need to situate themselves as learners of the craft of writing and engage

in the discourse of the craft, and students will engage in mastery learning when they adopt the cultural models of the craft. Learning the craft of writing requires the valuing of writing skills, learning the discourse of the craft, and the adoption of the cultural norms and ways of thinking inherent within the discourse. As such, the goal of becoming a good writer is intertwined with the adoption of mastery motivational goals.

Conclusion

Sociocultural motivation theorists are concerned with the social origins of motivation but recognize that individual motivational processes are neither determined by nor reducible to social processes. They use ideas from the Vygotskian tradition, such as the ZPD and transformative internalization and externalization, to explain how motivation has social origins yet individual agency and the relative autonomy of individual motivational processes are acknowledged. These notions have been prominent in sociocultural-motivation theoretical writing and in some of the empirical research reported, and this trend is likely to continue in the future with investigations involving areas such as the ZPD, intersubjectivity, and caring interpersonal relationships also becoming more prominent. Motivation theorists are also likely to explore other sociocultural perspectives, not explicitly based on Vygotskian ideas, in their attempts to explain the social origins and social construction of motivation. Investigations of the social origins of classroom motivation may increase in number as the trend toward studying motivation in naturalistic classroom contexts (Jarvela and Volet, 2004; Perry *et al.*, 2006) continues to gather momentum since classrooms are inherently social environments and are therefore best researched through theoretical approaches which recognize the social nature of motivation.

Glossary

Computer supported collaborative learning

(CSCL) – CSCL is a method of supporting collaborative learning using computers and the internet. The purpose of CSCL is to scaffold or support students in learning together effectively.

Contextual motivation – Motivation is no more a separate variable or a distinct factor, which can be applied in explanation of an individual readiness to act or learn – but reflective of the social and cultural environment.

Self-regulated learning – Self-regulated can be used to describe learning that is guided by metacognition, strategic action, and motivation to learn.

Socioemotional aspects of learning – Study of an interaction of affect and cognition including especially motivation and emotion in social interaction.

Introduction

Over the last few years, information and communication technology has opened up new avenues for designing learning and instruction. Technology-supported environments provide arenas for social, interactive, shared, and collaborative activity, as well as new tools for individual learning – in education and the workplace context. Computers are used to facilitate and redefine learning interactions, including those among students, those between students and teachers, and those between students and others in the broader out-of-school community (Renniger and Shumar, 2002). At the same time, these new and more open environments are characteristic of modern society: for example, they are complex, dynamic, less structured with mixed-motive situations, and contain multiple competing, or even contradictory, adaptive demands. Researchers often assume that technology-supported learning environments will sufficiently motivate and cognitively engage students as they study, interact, and collaborate in variety of virtual, computer supported, and online environments. This assumption may not be well founded. Although (often) constructivist-based learning environments incorporate features that may enhance student motivation to learn and

cognitive engagement far more than traditional classrooms, these environments also introduce difficulties that may interfere with students' willingness to engage.

Technology-Supported Learning Environments

During the past 20 years, technology has played an important role in many attempts to create powerful learning environments for supporting learning for understanding (De Corte *et al.*, 2003). From the beginning, the effects of the various forms of computer use on students' learning and motivation and social behavior have been a source of debate and a topic of continuing research. In the early years, the interest in research on motivation and social aspects was minor since the main interest was dealing with more cognitive-oriented research – essentially, to what extent working with computers affects what one does and how well one does it. One of the characteristics of that time was to use the power of new technology for the so-called solo-learner model and to find opportunities to individualize the learning process (Collins, 1986; Papert, 1980; Taylor, 1980). During the past 10 years, the situation has changed. Most of the recent research on the use of information and communication technology in education is more or less explicitly considering technology's possibilities for facilitating social interaction between teacher and students, and among students (Dillenbourg *et al.*, 2008; Barab *et al.*, 2004). Many of the current studies focus on computer-supported collaborative learning facilitated by different network-based collaboration tools and a learning theory based on pedagogical ideas (Koschmann *et al.*, 2002; Srijbos *et al.*, 2003). There is also increased ongoing discussion about online learning, virtual interaction, and wireless devices as cognitive and interactive tools in academic learning, as well as about learning at work (Pea and Maldonado, 2006; Renniger and Shumar, 2002).

Influence of Pedagogical Features in Technology-Supported Learning Environments on Motivation

In contrast to traditional school settings, which are usually well prepared, organized, and controlled by the teachers, the goals of self-organized learning and true student responsibility characterize these new technology-supported

pedagogical cultures (Hartley and Bendixen, 2001). The shift from teacher centeredness toward students' activity presupposes strong self-regulative efforts from students and, at the same time, offers more space for the individual's activities (Edelson *et al.*, 1999). This kind of meaningful and close relationship toward the learning tasks also helps students increase their intrinsic motivation and interest (Järvelä *et al.*, 2001). In addition, the often-mentioned increase in authenticity or anchored instruction to real-world problems with technological simulation or multimedia may have motivational implications (Cognition and Technology Group at Vanderbilt, 1996).

One recent pedagogical model applied to technology environments deals with problem- and inquiry-based learning (Brown and Campione, 1996; Edelson *et al.*, 1999). These pedagogical ideas' contributions and motivational implications are quite clear. The process of knowledge-seeking inquiry starts from cognitive or epistemic goals that arise from the learner's cognitive needs and that cannot be achieved by relying on available knowledge. The learner has a close and meaningful cognitive relationship with the learning task, which contributes to the intrinsic quality of motivation (Ames, 1992).

A technology-supported learning environment can also change the nature of social interaction (Bliss *et al.*, 1999). It presupposes collaborative activities, which usually lead toward the sharing of cognitive achievements with other students and members of the learning community (Stahl, 2004). Although there are contradictory findings concerning the success of collaboration in learning (Salomon and Globerson, 1989), some aspects of social interaction carry motivational implications. For example, peers provide models of expertise. Observing the progress of other students may increase confidence in one's own ability to succeed (Bandura, 1997). Furthermore, peer models provide a benchmark for the students' self-evaluations, thereby helping them to set proximal or more accurate goals (Schunk, 2001).

Collaborative learning, with and without technology, includes a variety of shared processes where individuals aim to regulate the prerequisites for learning together, and an increasing amount of studies emphasize the meaning of motivation and emotions for successful collaboration (Crook, 2000). Social learning situations, where the individuals' characteristics, goals, and demands meet, can evoke emotions and create novel motivational challenges for them (Järvelä *et al.*, 2000; Thompson and Fine, 1999). In collaborative learning processes, these socioemotional conflicts can emerge due to a variety of reasons originating from, for example, individual differences, cognitive conflicts, or modes of interaction. For instance, collaborative learning models presume that group members create a shared conception of a task and then try to reach this goal by equally sharing the responsibility of the learning process (Roschelle and Teasley, 1995). This requires constant negotiation and argumentation between the students

as well as adjustment of individual conceptions and goals, especially when the context of learning is not a face-to-face situation, that is, virtual or computer mediated. Often, the same situations are also socioemotionally challenging and can act as competitive motives, interruptions, or obstacles to motivated action in different phases of the learning process (Järvenoja and Järvelä, 2005).

Empirical Findings on Motivation and Emotion in Technology-Supported Learning Environments

Although there is evidence that students respond positively to the technology-supported learning environments designed according to the constructivist learning theory principles (e.g., Hickey *et al.*, 2001; Mistler-Jackson and Songer, 2000), it remains unclear whether students who enthusiastically participate do get cognitively involved. At the moment, there are not enough systematic empirical research and findings about specific motivational components, such as goals, self-beliefs, efficacy, or values; however, there is increasing interest among motivation researchers to extend their analyses to the new learning contexts.

The investigation of the role of goals and goal orientation has been an important recent development in the achievement motivation theory and research on learning and motivation (Pintrich, 2000). Goals are generally defined as perceptions about the purposes of achievement behavior, representing the meaning that individuals assign to achievement situations (Dweck, 1986). The findings indicate that computer-supported inquiry learning seems to foster productive task-related interaction and enhance student motivation in general (Blumenfeld *et al.*, 1991; Hakkarainen *et al.*, 2002). Similar findings on more enduring adaptive tendencies have been reported in other studies of student learning in computer-supported environments, applying socioconstructivist pedagogical models (CTGV, 1992; Hickey *et al.*, 2001). For example, the findings of Hug *et al.* (2005) in project-based science learning show that student interactions with technology scaffolded their engagement. The students in the study by Hug *et al.* learned to ask meaningful questions and discuss the ideas behind these questions. Järvelä and Salovaara (2004) compared students' achievement goals between the computer-supported collaborative learning group and the control group and found statistically significant differences in learning orientations. In the computer-supported collaborative learning group, learning orientation was maintained during the 3 years of the study, whereas in the control group, it decreased. The findings indicate that when students work in computer-supported and inquiry-based environments, they are engaged and work on the task because they have more freedom to choose their tasks and apply individual learning goals and strategies (Veermans and Järvelä, 2004).

Self-regulated learning has been defined as an active, constructive process whereby learners set goals for their learning and then attempt to plan, monitor, regulate, and control their cognition, motivation, behavior, and context (Boekaerts *et al.*, 2000). It is generally acknowledged that technology-supported learning environments are facilitators for the acquisition of self-regulatory skills (Boekaerts, 1999). The issues of openness, choice, and control of learning tasks in technology-supported environments compared to traditional learning environments may especially stress the individual students' volitional processes. Salovaara and Järvelä (2003) have shown that computer-supported collaborative environments enhance strategy use and intentional learning. Students reported deep-level cognitive strategies such as monitoring and creating knowledge representations and more collaborative information sharing compared to control participants. Similar findings were received in the study by Shell *et al.* (2005) where students' working with established computer-supported collaborative classes reported more knowledge-building goals and more question asking than fellow students. Whipp and Chiarelli (2004), in turn, investigated students' self-regulation in a web-based course. They studied how higher education students used and adapted traditional self-regulation strategies to complete tasks and cope with challenges in a web-based online course. According to their results, the students not only used many traditional strategies, but also adapted planning, organization, environmental structuring, help-seeking, monitoring, and self-reflection strategies in ways that were unique to the online technology context.

There are also less-adaptive consequences to technology-supported learning in terms of students' socioemotional interpretations. The responsibility of setting up one's own learning goals and monitoring one's own learning activities in various online learning environments and computer-supported inquiries can also be quite demanding for some students (Veermans and Järvelä, 2004). Earlier research in traditional classroom learning contexts has shown that there are individual differences in students' dispositions toward challenge, with some responding positively and others avoiding taking up difficult work (Meyer *et al.*, 1997). Moreover, there are also within-student individual differences in terms of how a student may respond to a given task across an inquiry unit (Patrick and Middleton, 2002).

In general, academic emotions are significantly related to student motivation, learning strategies, cognitive resources, self-regulation, and academic achievement (Pekrun *et al.*, 2002). Nevertheless, not only do the emotions themselves vary, but also the sources that cause emotions. Learning situations are important sources of emotions that instigate variety of self-referenced, task-related, and social emotions (Meyer and Turner, 2002). Concerning technology-supported learning environments and students' emotional expressions, Järvenoja and Järvelä's (2005) study investigated

what kind of explanations the students give to their emotional experiences related on computer-supported collaborative learning. One of the critical features found was that, especially in the beginning of the learning project, the self-driven emotions played an important role in order to inhibit or facilitate task involvement. Volet and Wosnitza's (2004) study examined the origin, direction, and impact of emotions in social online learning. Their analysis of social online-learning situations revealed a range of other-directed emotions, in addition to self-, task-, and technology-directed ones. Emotions generated in social online environments are not different in nature from those generated in face-to-face learning situations. What is different in social online learning is the fact that emotions are expressed through technology, and that the disclosure of emotions is necessarily voluntary. The results highlight the multiple directions that emotions can take and the significance of students' interpretations of their emotions on the learning process.

Theoretical Approaches to Investigate Motivation in Technology-Supported Learning Context

While the aim of research has been to understand socioemotional processes in a technology-supported learning environment, there has also been an interest in understanding the learning process by, with, around, and through the computers. The leading questions have been: How does interaction between student motivation and situational features of the technology-supported environment take shape? How do different students cope with the demands of a situation and what is the potential provided by the features of the learning context to their motivational interpretations?

The overall picture of the learners' adaptation to educational environments has increased the researchers' interest in better understanding the interaction between personal and contextual factors in the motivation and achievement of students (Pintrich, 2000). Through the influence of sociocultural and situated cognition theories, it has been recognized that the motivation of individual learners is also influenced by social values and the context in which the learning takes place. Motivation is no longer a separate variable or a distinct factor, which can be applied in explanation of an individual readiness to act or learn – but reflective of the social and cultural environment (Järvelä and Volet, 2004).

The notion of contextual motivation has been widely debated over the last few years (Anderman and Anderman, 2000; Hickey, 1997; Volet and Järvelä, 2001). Conceptualizing motivation in learning contexts builds upon the situated learning paradigm, which views the process of learning as distributed across the learner and the environment in which knowing occurs, and the activity in which the learner is participating (Anderson *et al.*, 2000). This conceptual

framework has provided a useful foundation for understanding students' goals, intentions, and emotions across situations – in real contexts and real time, and the context–person mutual influences have been highlighted in various technology-supported learning environments (Järvelä and Niemivirta, 2001).

Another tendency in research has been to extend the individual analyses of self-regulated learning and motivation to social settings mainly because social and collaborative aspects are emerging features in technology-supported learning models. Although self-regulation research has traditionally focused on the individual perspective (Boekaerts *et al.*, 2000), there is increasing interest in considering the mental activities that are part of self-regulated learning at the social level, with reference to concepts such as social regulation, co-regulation, and shared regulation (McCaslin and Hickey, 2001; Salonen *et al.*, 2005). With regard to the role of the social aspects of learning, these models have examined how the social context plays a role in the generation of cognitions and pursuit of personal goals and, alternatively, how individuals regulate their social context – among other objects of regulation such as cognitions, motivation, and emotions – in order to achieve their goals.

Methodological Challenges

When considering the methodologies for studying the socioemotional aspects of technology-supported learning, challenges remain. The earlier mainstream research on motivation, which acknowledges the impact of context (e.g., research on perceptions of classroom goal structures, see Ames, 1992), explains it on the level of goals, for example, but context is not made operational in real time with real tasks, the here and now of learning. Time perspective is longitudinal or cross-sectional, but not online. Another methodological limitation deals with empirical evidence with social dimensions of motivation.

The value of qualitative methods has lately received recognition in educational psychology, in general (Patrick and Middleton, 2002; Perry, 2002), and in classroom motivation research, in particular (Dowson and McNerney, 2003; Turner and Meyer, 2000), where it has traditionally been neglected more than in general educational psychology. A reason for this recognition is that the educational research had changed progressively from laboratory settings to real-life classrooms. A growing number of researchers have adopted a person-in-context perspective and a multimethod approach to investigate students' situational adaptations in a classroom learning context (Järvelä *et al.*, 2001). In this perspective, motivation is constructed in the interplay between an individual and a context. Usually, this type of research involves the application of qualitative methods, combining qualitative and quantitative approaches, gathering of process-oriented

data, and the use of various units of analysis (Butler, 2002). Recently, new tools have been developed that collect detailed information about students' studying actions by logging the time and context of every learning event (Winne *et al.*, 2006). These traces recorded in a computer program are artifacts of tactics and strategies in a log of fine-grained, temporally identified data that can advance research about how learners engage in learning.

Conclusions

It is known from the research tradition of many centuries that certain motivational processes, such as goals, emotions, and strategies, are the core elements of the learning process. Technology does not question the relevance of these constructs, but calls for us to focus on different perspectives of learning with these theoretical elements. In the future, we should concentrate on finding the critical elements of context that interact with a person – not the technology itself or other contextual features of the environment which, anyway, continuously change.

Introduction

In studies of learning in educational settings, researchers find that students often have conflicting yet equally valued goals. For example, one student, during an introduction to life science, may want to fit in with their peers, pursue questions that interest them, and perform successfully. Even after having committed to a school task, some students find that obstacles and sidetracks lay between start and completion. Completion of tasks can be supported by conscious self-regulation; but students cannot consciously manage every roadblock, stray thought, or discomfort without dividing their attention. In addition to conscious regulation of cognition as they work, students often have implicit, habitual, or automatized processes in place to maintain their effort. Together, these different aspects of self-regulation are what allow for volitional functioning.

Educational researchers disagree about the utility of the concept of volition. Early theory in psychology equated volition with the idea of willpower and misleadingly considered volitional struggles as a sign of personal weakness. Some theorists question the need for volition as a research target because established concepts of efficacy and agency seem sufficient to explain the successes of effective learners (Zimmerman and Schunk, 2002).

Other theorists find explanations of purposive action incomplete without the concept of volition (Gollwitzer, 1999). Motivation leads to commitment but volition denotes follow-through. Volition, defined in modern theory as purposive striving, entails processes by which students implement goals during learning, sustain motivation, and strategically regulate cognition and affect (Corno, 1994). Through volitional control, students regulate emotion, sustain motivation, and manage their learning. Volition is a target for intervention when learners stop short of perseverance in the face of difficulty and distraction, avoid learning projects that require focus and persistence, or fail to develop effective academic work habits. A full explication of goal pursuits in education requires accounting for both motivation and volition.

Our task in this article is to move beyond debates about construct utility, and keep readers in touch with some basic evidence supporting the importance of volitional control in academic learning and performance. Research on volitional control of learning provides valuable insights into how students who want to learn (i.e., students who are already motivated to learn) manage the learning process.

This includes an understanding of self-referenced processes used to cope with distractions and persist in accomplishing goals. Researchers have studied volitional control at different levels:

- as a relatively stable, self-reported orientation or work style that distinguishes different types of students (see, e.g., Kanfer and Heggstad (1997) who study motivational traits; Higgins (1989) who studies self-guides; and Koole *et al.* (2005), who discuss a temperamental predisposition they call action orientation);
- as a recordable process or event influenced by context (e.g., Winne and Jaimeson-Noel, 2003; Xu and Corno, 1998) and
- as an implementation mindset or state that can be induced experimentally by asking students to state exactly where and when they will do assigned work (Oettingen *et al.*, 2004).

A relatively recent body of research, conducted cross-nationally over the past three decades, has become the basis for successful intervention programs, and resulted in useful guidelines for parents and teachers hoping to build good academic work habits in children.

This article is divided into two substantive sections. First, we illustrate how researchers have studied the psychological construct of volitional control in education at different grade levels, highlighting methodologically valid and reliable procedures for capturing the construct. We describe key relationships between aspects of volitional control and educational accomplishments. In the next section, we provide brief descriptions of educational interventions designed to improve learners' volitional control. These interventions have produced positive outcomes at primary, secondary, and postsecondary levels of education.

Understanding Volitional Control in Education

Emotion control, effort management, and good academic work habits are manifestations of volitional control that contribute to successful performance in educational settings (Boekaerts and Corno, 2005). Evidence from different disciplinary and theoretical frames indicates that even young students can strategically manage their own learning. Recent research focuses on emotional regulation as a key aspect of volitional control, and demonstrates its value to

emotional wellbeing. Emotions can also serve as support functions in learning (e.g., they can signal the need to alter a course of action) but they must be channeled productively (Turner and Schallert, 2001).

Effortful Control

The social psychologist, Walter Mischel devised the classic protocol for studying impulse control in young children (see Mischel and Mischel, 1983). In a series of experiments, children as young as 4 had to resist the temptation to touch a desirable object while they sat alone in a room awaiting the return of a researcher. If they successfully avoided touching the object for a specified period of time, the object would be theirs. Observations of the children as they waited showed that those who delayed gratification sang songs and talked to themselves, looked at something else in the room, or played finger games to refocus their attention and help to fill the time. The authors' interpretation was that these children focused their mental energy and controlled their impulses and behavior in order to reach a goal. They were motivated by the goal, but they called forth volitional resources to accomplish it.

The relevance of this research to education was demonstrated some years later when Mischel and his colleagues reestablished contact with families of many of these same children (Shoda *et al.*, 1990). Using correlational procedures to relate early delay time with meaningful outcomes of education, the authors found that students who had been able to delay gratification and self-regulate at age 4 had significantly higher academic achievement and positive parental assessments of adjustment than students who had demonstrated weaker impulse control as children. Although correlation does not imply causation and the sample size was small, this was the first study to make such a longitudinal connection. Mischel and his colleagues established the value of focused attention in children's impulse control. Their analyses stressed the underlying importance of self-instruction and self-motivation strategies used by children as mediators for goal accomplishment, and provided a link between these variables and educational growth.

Mischel's protocols have been used subsequently in other examinations of delay in children (e.g., Kochanska *et al.*, 2000, 2001; Li-Grining, 2007). Strategies associated with delaying gratification are now considered part of a class of self-regulatory mechanisms broadly referred to as effortful control (Rothbart and Ahadi, 1994). Eisenberg *et al.* (2005) have extended research on impulse and effortful control in children.

These authors studied the development of effortful control throughout infancy and childhood in a controlled setting with a large sample size over more than 20 years. They found that individual differences in effortful control

are established in the first years of life, and that environment and parental support is crucial to the development of self-regulation skills (Zhou *et al.*, 2007). This combination of work from the subdisciplines of social and developmental psychology underscores the need for researchers and educators to consider both dispositional and situational factors in addressing students' self-regulation and effortful control.

Developmental researchers who have focused on the examination of effortful control have frequently conducted their research in controlled laboratory settings or through examining parent-child dyads. Students use volitional strategies to support their effortful control in a variety of complex situations: when learning material is not very interesting but students desire to do well; when others in the classroom are distracting; when the relationship between outcome and performance seems unclear; or when there is a need to prioritize a work goal relative to a competing social goal (Corno, 2004). Volitional resources include, but are not limited to, strategic self-instruction to tone down negative affect (Kuhl, 2000), vigilance or self-monitoring (Posner and Rothbart, 1992), structuring and organizing the environment to maximize focus and minimize intrusion (Xu and Corno, 1994), and seeking aid from peers and teachers to bolster persistence (Newman, 1994).

Emotional Regulation

Distractions and roadblocks to learning not only occur externally, but also internally. To be successful at self-regulation, students need to manage their emotional states, as well as their cognitive and motivational environments when they complete academic tasks. Although students experience a wide range of emotions in educational contexts, performance anxiety is a particularly prominent internal obstacle (Stober and Pekrun, 2004). Academic work provokes anxiety in many students; this has been demonstrated through physiological measures (Spangler *et al.*, 2002), surveys (Pekrun *et al.*, 2004), experimental manipulations (Meinhardt and Pekrun, 2003), case studies (Pekrun *et al.*, 2002), and analyses involving multidimensional scaling (Schutz *et al.*, 2002). Students' ability to control anxiety, keeping it at an optimal level, is critical if they are to accomplish their academic goals. This aspect of volitional functioning is supported by affect-regulation strategies.

Affect may be regulated deliberately or automatically as a function of temperament or predisposition (Koole and Jostmann, 2004). Deliberate regulation strategies include slowing one's breathing, reappraising the importance of the task, reminding oneself of personal agency (Schutz *et al.*, 2004), and clearly framing a task completion goal (Boekaerts, 2002). Individuals' temperament or predisposition determines the degree to which they instinctively regulate surprising or unpleasant stimuli by approaching or avoiding (Langens and Morth, 2003).

To be successful at managing emotions, students who are predisposed toward worry and emotionality will benefit from emotional scaffolding. Teachers can provide support and help anxious students to manage appropriate emotional responses to educational challenges. For example, Rosiek (2003) documented how teachers could profitably engage students' curiosity, interest, and even anger as a way of helping them connect to important content. When teachers engage students' emotions, however, it is critical that they provide the support to channel the emotion toward engagement; scaffolding is about engaging some emotion but not too much.

Managing the Tasks of Learning

Managing the tasks of learning similarly requires both deliberate and automatic sources of regulation. Some aspects of school learning tasks are controlled by teachers and curriculum design – sequencing, for example, and pacing. However, students must manage other aspects of tasks deliberately – setting completion goals, budgeting time, and seeking feedback. At a more habitual level, effective task management by students includes localized self-monitoring and selectively attending to pertinent details – error checking, self-instructing, and avoiding distraction.

An example of automatic or intuitive regulation that benefits a task is provided in a study by Snow and Lohman (1984). These authors examined component processes used by test takers when completing standardized tests. From a variety of indicators, they demonstrated that automatically applied organization and control processes were a critical aspect of self-regulation for scholastic achievement. In addition, this research showed that automaticity came about through exercise and appeared to be transferable to situations with similar affordances and constraints (Stanford Aptitude Seminar, 2002).

Implicit control processes, which students are often unaware of, can be made explicit if they are reframed as strategies for attacking tasks or problems. Corno and Kanfer (1993) asked high school and college students to think deeply about and explain how they manage different forms of academic work (homework, problem-solving tasks, and facing difficulty – situations that require effortful processing). Covert strategies (internal to the student) included meta-cognitive control (e.g., make a plan to follow and jump in), emotional control, (e.g., imagine being good at this and how that feels), and motivation control (e.g., give myself instructions about timelines). Overt strategies included control the task situation (e.g., move away from distractions) and control others in the task setting (e.g., tell the teacher if he/she is not being clear; see also McCann and Turner (2004) who developed an academic volitional strategies inventory).

Conscientious students with a good repertoire of both covert and overt strategies will use them adaptively, as appropriate for different tasks and circumstances. As strategy use can require effort, however, consistent conscious strategy use is a challenge for many students, even when they receive direct strategy instruction (Butler and Cartier, 2004; Dewitte and Lens, 1999; Pressley *et al.*, 1990).

Academic Work Habits

Recently, researchers have combined measures of volition obtained from different sources of data as a means to increase reliability and predictive validity. For example, Duckworth and Seligman (2005) defined self-discipline as an indicator of good work habits in high school students. To operationalize the construct, they obtained two independent samples of students from the same magnet school, and combined subjective ratings by students of how they worked (self-reports), objective observations from teachers and parents who rated students on the same qualities, and a performance-based measure (a delay-of-gratification task) modeled after Mischel and Mischel (1983) but designed for older students.

Regression analyses conducted using final grade point average (GPA) as an outcome measure controlled for two related variables: general ability (the Otis–Lennon School Ability Test) and prior GPA. Results showed that the self-discipline composite accounted for over twice the variance attributable to the general ability measure, and 16–20% of the variance beyond that accounted for by prior GPA. Further study showed that the highly self-disciplined adolescents outperformed their peers on achievement tests, high school attendance, and even admission to a selective high school (p. 939).

Although studies such as this give evidence to support the value of good work habits, less well studied are questions about how good work habits develop, and how ineffective habits can be changed (Corno, 2007). As noted above, some research has shown that students' automatic responses to learning tasks can be brought under greater conscious control through training (Bryan and Burstein, 2004; Maes and Karoly, 2005). Other research has suggested that students with poor work habits need more support in their homes and schools; for example, poor work habits are more common in students who attend impoverished schools (Battistich *et al.*, 1995).

Socio-demographic challenges affect the development of children's cognitive organization and control processes but appear unrelated to indicators of impulsivity, which can be temperamental (Li-Grining, 2007). These findings imply that explicit instruction and scaffolding in self-regulation may be especially important for temperamentally impulsive children who come from high-stress backgrounds. One hypothesis is that these children may have fewer effective

models of volitional functioning in their home environments (i.e., an access problem); alternatively, the stress these children experience may interfere with their ability to engage the cognitive resources needed to attend sufficiently to the volitional models they observe (Perry, 1998). Both hypotheses could also be correct; their delays could be compounded; in any case, explanations such as these deserve close investigation.

Selected Intervention Programs in Self-Regulation

Over the past 20 years, educational psychologists have developed a number of intervention programs designed to help students become more effective and efficient learners (Kauffman, 2004). Many of these programs have been studied empirically, but only a subset focused on helping students to function volitionally. Each program that we subsequently discuss included an evaluation component, and targeted at least one aspect of volitional functioning described above.

Elementary School Settings

Harris *et al.* (2005) developed a self-monitoring intervention to support on-task behavior in students diagnosed with attention-deficit/hyperactivity disorder. Students were instructed on two systems: one to help them self-monitor attention and one to self-monitor performance. To monitor attention, students were instructed to note their attention (checking “yes” or “no” on a chart provided for them) after hearing a tone played at the end of a random interval from 10 to 90 s in length. At the end of each study period, the child would mark on a graph the number of times they answered “yes.” To self-monitor performance, the students were asked to graph the number of times they practiced their weekly spelling words. Both interventions showed statistically significant improvements to students’ on-task and spelling study behavior. Aids and instructional support for self-monitoring exercises such as those used by Harris and her colleagues can also be found in Zimmerman *et al.* (1996).

Elementary school teachers have been the focus of other interventions designed to teach or develop self-regulation in students. Perry *et al.* (2004) developed a mentoring program to support preservice elementary school teachers integrating self-regulation strategies into their curriculum. The teachers in their study addressed all phases of self-regulated learning in their lesson plans, that is, planning, implementation, and reflection. An extensive evaluation across five cohort groups found that the teachers who designed complex tasks (e.g., multiple goals, extended activities over time, a variety of processes, and alternative ways for children to demonstrate competence)

provided significantly more opportunities for students to engage in and successfully develop self-regulated learning skills. For example, students were more likely to have choices, control over challenge, opportunities to evaluate their learning, and collaborate with peers.

Middle School Settings

The strains of adolescence put middle school students in the United States (ages 12–14) at an important period in their academic development; the expectations that students’ set at this point in their lives carry over into their future academic and career choices (Tai *et al.*, 2006). Oyserman *et al.* (2002) developed the Pathways for Youth project, a 9-week, after-school program for urban middle school students. The program was designed to support students’ self-regulation and academic performance. Adult guides worked with students to complete seven steps:

1. envisioning possible futures for themselves,
2. conceptualizing those futures as goals,
3. constructing a path for goal obtainment,
4. making explicit connections between present educational activities and the valued future goals,
5. discussing possible roadblocks and forks in the path,
6. brainstorming strategies for managing imagined future obstacles, and
7. interviewing successful adults from the community about their own strategies for reaching goals.

This process supported students through the full self-regulatory cycle from goal setting or motivation to volition (see Corno, 1995). A controlled intervention showed that relative to students in a comparable group, students who participated in the program “. . . reported more bonding to school, concern about doing well in school, ‘balanced’ possible selves, plausible strategies to attain these possible selves, better school attendance, and for boys, less trouble at school” (Oyserman *et al.*, 2002: 313).

Randi (2004) provided opportunities for preservice teachers to generate ways to develop students’ volition as they transitioned from college student to teacher in their teacher-education program. Most of Randi’s teachers were planning to teach in grades 5–8. Their 13-week course focused on motivation and volition theory and classroom applications of self-regulated learning. Working in small groups, students read the research literature, analyzed teaching cases, and wrote about self-regulation strategies they themselves used to follow through on their commitments to become teachers. Teachers also wrote weekly journal entries reflecting on strategies for self-regulation they would use in their own classrooms, and designed curriculum activities and lessons for their students. The coursework led to many examples of units, incorporating self-regulated learning that these teachers could then take into their own middle school classrooms.

Secondary School Settings

The Interactive Learning Group System (ILGS) innovation program (Boekaerts, 1997; Boekaerts and Minnaert, 2003) is an example of a school-wide self-regulation intervention. The project targeted vocational secondary schools in the Netherlands by providing students with ill-structured problems in a highly structured environment. Instructors were trained in self-regulation-based instructional principles. Examples of these principles were “prepare group assignments at home and write them on the blackboard as soon as you enter the classroom. . . so that teachers come to class with an explicit plan and that students are aware of the amount of work to be done”; and “prepare the students for group assignments by providing prior knowledge.” The teacher “modeled the learning processes, making them more transparent to students” (Rozendaal *et al.*, 2005: 144). Another aspect of this program required students to work in interactive, heterogeneous groups on ill-structured problems. Although the intervention was not fully implemented by teachers as planned, the program found some success in providing teachers with insights into students’ self-regulation and changing psychological needs.

Randi (Randi and Corno, 2000) developed and tested a program for teaching high school humanities students about self-regulated learning using a literary quest theme. Students gained an intellectual understanding of the concept by reading about self-regulating characters in the quest literature, and then applied their knowledge by writing about such strategies in their own lives. Students exposed to this curriculum were able to explain the strategies of self-regulation through their writing, and accurately discussed the utility of volitional control in their own lives.

Undergraduate Settings

Several undergraduate programs to support students’ study habits and strategic learning have appeared over the past 25 years. Most programs provide instruction in cognitive learning strategies, and also help students achieve the goals they set for themselves in their pursuit of higher education. In a 5-year, longitudinal study at the University of Texas, Austin, Weinstein *et al.* (1998, 2000) evaluated a learning and study strategies course. This three-credit, nonmajor, educational psychology course was not only designed to focus on cognitive learning strategies, but also provided students with instruction on explicitly using affect and volitional strategies. The evaluation found that 71% of students who successfully completed the course in study strategies had graduated after 5 years, compared to 55% for the general university population, despite the former having entered with lower Scholastic Aptitude Test (SAT) scores. The effectiveness of acquiring volitional strategies could not be separated from the learning of other strategies in this evaluation, however.

Conclusion and Recommendations for Future Research

Volition, defined as purposeful striving, is a useful and necessary concept that complements motivation. Most research on volitional control in academic settings is based on students’ reports of their thinking and behavior that are quantified on ordinal scales and used to predict performance (McCann and Garcia, 1999; Pintrich and Garcia, 1991). However, some investigators have obtained observation data, used interviews, conducted case studies, and designed experimental tasks in order to elicit evidence of volitional control (see Corno, 2000).

Key components of volition include effortful control and emotional regulation. Effortful control of impulses first appears in toddlers, and is associated with positive social, emotional, and academic outcomes later in life. For students who have difficulty with emotional regulation, learning to use particular strategies can be productively channeled, particularly if they are constrained by predispositions such as stress or performance anxiety. Education practitioners can support students’ emotional regulation through instruction in volitional strategies and emotional scaffolding.

Managing learning tasks similarly calls upon both implicit and explicit processes of volition. Explicit processes include organization and control strategies that can be fostered through instruction and modeling. Implicit processes, such as avoiding distraction through focused attention to pertinent details in tasks, are less easily learned through instruction. Both types of processes underlie good work habits, however. Good academic work habits, those products of volitional functioning that come about from repetition of volitional strategies within supportive environments, are important to success in school. Teachers reinforce good work habits all along the age range, even into and through higher education (Corno, 2007).

Intervention programs for adolescents have been more prevalent than those for children and toddlers. Existing intervention programs focus primarily on supporting explicit self-regulation, study strategy use, and motivation through goal setting. A few programs support students’ affective regulation through collaborative learning and mentorship. Perhaps the best examples of programs that support students through all phases of self-regulation are those conducted by Oyserman, and colleagues.

This article is not the avenue for an elaborate agenda on future research on volitional control of learning. However, we can say from our review that there are few direct hypotheses about the aspects of volitional control that are most likely to promote academic success in students. Researchers have not assessed the added value of volitional strategies over and above the learning of cognitive skills. In addition, we argue that little is known about the optimal conditions for volitional control. Although

educational researchers know something about how to develop volitional capabilities in students, there is no evidence about why students from high-stress environments demonstrate volitional delays. We need to know which techniques for teaching volitional control transfer across contexts, and what obstacles may interfere with the adaptive use of volitional strategies in students who have learned them. As discussed previously, questions remain about how good work habits develop, and how ineffective habits can be changed. Finally, we argue that there is a need for more experiments designed to manipulate the covert and overt aspects of volitional control used by students in a variety of educational settings, classrooms, homework completed outside of school, and studying in online environments.

Subjective Well-Being

Since it came into discussion in the early 1970s, the idea of subjective well-being (SWB) has been strongly promoted during the last 20 years as an individual and social value as well as a basic psychological need (Diener and Lucas, 2000; Strack *et al.*, 1991). As such, SWB is an indicator of a quality of life and is important for human health and development. The basic aims of well-being research are to identify harmful influences and to support those which foster good health, and to prevent illness. Nowadays, research on SWB is central to positive psychology aiming to build a good quality of life (Linley *et al.*, 2006).

Approaches to SWB

Different research traditions on well-being resulted in different definitions of SWB (e.g., Diener, 1984; Larsen and Diener, 1987; Veenhoven, 1991). There are three main lines of conceptualization of SWB, which can be classified as follows:

- SWB is a specific emotional quality of feeling well.
- SWB is a supra-term for positive emotions like enjoyment, pride, satisfaction, etc.
- SWB is a multidimensional concept combining cognitive and emotional factors.

Despite their differences, all three definitions agree on enjoyment or happiness as a core element of SWB.

As a psychological term, SWB usually refers to a subject's own feelings and evaluations. For example, if a person is happy or proud and evaluates his/her actual situation positively, he/she is expected to feel well; if a person feels sad or angry and evaluates his/her situation negatively, he/she will have a low level of well-being. Feelings and evaluations depend on a person's previous experiences, expectations, goals, and values, that is, his/her reasons for positive or negative emotions and evaluations may differ. SWB also consists of both mental and physical components, that is, a person's thoughts as well as body sensations have to be considered. Defined in this way, SWB differs significantly from single evaluations like satisfaction, or from singular emotions like enjoyment. According to the WHO definition of health, SWB can be classified into psychological, physical, or social forms of SWB (e.g., WHO, 2000).

Because of the coexistence of positive and negative events in life, emotions and evaluations can be negative as well as positive. Consequently, SWB can be defined by the interaction of positive and negative aspects: The more positively life in general or specific relevant domains of life are experienced, the better the well-being; negative feelings and negative evaluations of important circumstances or events in one's life result in a low level of well-being. Thus, to understand and explain a person's SWB, positive and negative dimensions have to be taken into account simultaneously. A high level of SWB occurs when there is a dominance of positive emotions and evaluations over negative emotions and evaluations. The greater the difference between the positive and negative dimensions, the higher the SWB.

SWB can develop in a short- or long-term perspective (Becker, 1994; Kim-Prieto *et al.*, 2005). Short-term SWB is the expression of current positive emotions and cognitions toward an actual situation, for example, working together with a classmate on a problem during the mathematics class. Thus, it is situationally determined. Long-term, habitual SWB is sustainable and indicates a more general evaluation of life situation and circumstances, for example, feeling well in school on the whole. Habitual SWB develops through frequent experiences of short-term well-being, that is, repeated experiences of enjoyment, mastering of academic challenges, feelings of competence in school, and a low amount of negative occurrences will lead to well-being in school. However, habitual SWB is not a simple or accurate aggregation of actual SWB. Specific experiences of actual SWB can contribute differently to habitual SWB, in that actual SWB in situations of special importance can have a stronger impact on well-being than situations of lower relevance.

In order to avoid theoretical confusion and to enable empirical precision, the following differentiation can be suggested:

- There are general characteristics of SWB such as its duration.
- Indicators of SWB are forms of expressions of SWB, for example, being relaxed.
- Components of SWB determine the elements of SWB such as enjoyment or the absence of worries.
- There are accompanying phenomena to SWB, like good mood.
- As long as their causal influence lacks empirical evidence, variables which show a significant relationship to

SWB (like academic degrees) should be described as correlates of SWB.

- Predictors, causes, or sources are responsible for the development of SWB as is also true for positive incidents. Nevertheless, predictors themselves can, to some degree, be influenced by SWB, for example, a person experiencing a high level of SWB is likely to perceive more positive events.
- Consequences of SWB are factors which are influenced by SWB, for example, information processing.

There are a lot of different quantitative and qualitative instruments for the assessment of SWB, ranging from affect–balance–scales to well-being questionnaires to event sampling methods and happiness interviews (Andrews and Robinson, 1991; Diener, 1984; Diener and Biswas-Diener, 2000; Lucas *et al.*, 1996). Of special importance for the accurate assessment of SWB is a multifaceted approach. Various dimensions of SWB, for example, the emotional and cognitive, the positive and the negative, have to be considered. Single items are not able to measure SWB in its full sense and multimethod assessments which explicitly integrate different perspectives on well-being are recommended.

Predictors of SWB

SWB proves to be sensitive to several factors. For this reason, it is also depicted as a multisource phenomenon. The more generally well-being is defined and measured, the more sources can influence it, from weather to situational circumstances to subjective beliefs (Diener, 1984). As a consequence, it is necessary to specify specific predictors for the different components of SWB. Although researchers so far were not successful in uncovering the most potent variables, social integration plays an essential role for SWB. More generally, there is empirical evidence about the impact of the following factors (Hascher, 2004):

1. First, SWB is influenced by personal circumstances. Situational factors such as an individual's financial status and social integration are important for a positive evaluation and contribute directly to subjective well-being. Other situational factors, such as an individual's socio-economical status, are intertwined with specific resources (e.g., social contacts) which influence the fulfillment of goals and aspirations and as a result SWB (e.g. Diener *et al.*, 1995).

2. Second, SWB can be predicted by personality factors. In addition to gender, the dependence of SWB on introversion versus extraversion (two facets of the so-called Big Five) has been confirmed (e.g., Vittersø and Nilsen, 2002). Extraverted individuals experience more positive situations in life and, thus, feel better than more

introverted persons (the so-called Bottom-Up Approach). They also interpret life more positively, react in a more positive way to life events and circumstances, and feel better than more introverted individuals (the so-called Top-Down Approach).

3. Third, subjective differences exist on how life-events are evaluated and interpreted. A person's evaluations are based on different points of references (e.g., Stein *et al.*, 1997). These are, for example, social comparisons, individual goals and expectancies, processes of adaptation to new life-circumstances, coping with challenging situations, control beliefs, or causal attributions.

Common to all three approaches is the subject–environment paradigm: there is no mono-causal relationship, but it is the interplay of the subjects (e.g., their goals, experiences, and attitudes) and the environment (e.g., living and working conditions) which determines SWB.

Well-Being in School

Principally, evaluations about SWB are relevant for a variety of contexts and different branches. For example, during the last years, psychologists paid special attention to comparisons of the SWB of nations (e.g., Biswas-Diener *et al.*, 2005). Till now, educational research concentrated mainly on cognitive aspects of school or on a few socio-emotional variables like test anxiety or school climate. As a result, studies on SWB of students or teachers are not yet common. Nevertheless, there are important findings which need to be taken into consideration for designing powerful learning environments in school. Some of them result from empirical studies which were initiated or conducted by health education research.

Student well-being

Despite a lack of research, SWB is a pedagogical aim in educational theory and practice. Although nowadays broadly accepted, it has also been a controversial topic (Boekaerts, 1993). Skeptical voices doubt the solely positive function of SWB and ask if student SWB could be harmful. They are afraid of neglecting the attainment of academic goals for the benefits of a positive atmosphere in school.

However, good reasons exist to foster SWB in school. Apart from the fact that SWB in school is a value in itself, there is empirical evidence that SWB affects students' learning processes and learning outcomes positively. Although SWB might not directly enhance student achievement, it is intertwined with various factors that contribute to effective learning and is an important criterion for a positive school climate which is necessary for students' learning – especially in highly structured, achievement-oriented, nonoptional learning contexts such as schools (e.g., Mayring and von Rhöneck, 2003).

Students who feel well in school can develop positive attitudes toward school learning and achievement. SWB can also serve as a resource for coping with negative peer influence or drug abuse. Furthermore, student SWB is a crucial indicator for children's and adolescents' health status and is a mirror of school quality.

Definition and research lines

There are various views as to how one could investigate student SWB. One important aspect is how student SWB is defined. Another differentiation stresses the question of whether SWB is an input or an output indicator of school quality. The different ways of operationalization can be described as follows:

1. Students are asked about aspects of their mood states, mostly negative states like depression (e.g., Benjet and Hernández-Guzmán, 2002; Undheim and Sund, 2005). Although SWB is not directly addressed, the analyses are subsumed under the term SWB. Sometimes direct correlations to school variables (e.g., school adjustment) are investigated. However, SWB itself is not investigated, neither in a general sense nor focused to the specific school situation.

2. Students are asked about their SWB by using a general well-being scale for children or adolescents (e.g., Jin and Moon, 2006; Konu *et al.*, 2002). These questions are directed toward life in general. Both dimensions of SWB, positive (like enjoyment) and negative (like worries), are addressed but the focus remains unspecified. Sometimes, additional instruments on school variables like satisfaction with school or school adjustment, which are related to general SWB are integrated. SWB itself is not yet directed to the specific school situation.

3. SWB in school is operationalized by a selective combination of various emotional, social, and cognitive school-related variables, for example, test anxiety, social integration into the classroom, and satisfaction in school (e.g., Eder, 1995). Nonetheless, there is no clear or explicit definition of SWB, rather an argumentation why the selected variables represent well-being.

4. Psychological well-being as a specific quality in the specific school setting is the central variable of research, described as student SWB, SWB of pupils or school SWB, or SWB in school (e.g., Engels *et al.*, 2002; Hascher, 2003, 2004, 2007). Until recently, only a few instruments existed but new ones are being developed and used and the results for student well-being, its correlates, and predictors are presented.

5. In terms of the WHO definition of health, student SWB is discussed under the broader perspective of health and health promotion (e.g., Konu and Lintonen, 2005, 2006). As school is an important context for children and adolescents, SWB in school is conceptualized as a crucial component of general physical and mental health.

So far, empirical studies of student SWB often used single items only, to ask them if they feel well in a learning situation, in a lesson, or in school in general. However, SWB in school as a psychological concept represents not a singular impression, but a more holistic quality of students' subjective experience in school with cognitive and emotional elements: student SWB in school is a quality of experience characterized by the dominance of positive feelings and cognitions toward school, persons in school, and the school context in comparison to negative feelings and cognitions toward school life. Well-being in school represents positive, emotional, and cognitive evaluations of school reality (Van Petegem *et al.*, 2006). It can be seen as an imbalance of positive and negative aspects in favor of positive aspects.

According to multidimensional concepts of general well-being, student SWB can be assumed to consist of a number of dimensions. Six dimensions prove to be crucial for student SWB (Grob *et al.*, 1996; Hascher, 2004; Ryff and Keyes, 1995):

1. positive attitudes and emotions toward school in general,
2. enjoyment in school,
3. positive academic self-concept,
4. absence of worries about school,
5. absence of physical complaints in school, and
6. absence of social problems in school.

How do students feel in school?

In asking this question one uncovers an amazing incongruity: researchers found that school is a highly aversive context and a central source of stress for some children and for many adolescents. When asked about daily experiences in school, students report a clear dominance of negative situations and emotions. Yet, most students indicate middle, some even high, score when asked about their SWB in school. One possible explanation for this discrepancy is that the results depend on the way students are asked about their school. To report about everyday events in school may lead to a focus on negative aspects because of their stronger need to be communicated. Conversely, a questionnaire on student SWB stresses negative as well as positive components, and thus, is able to take both sides of school into consideration simultaneously. Another explanation is given by the theoretical assumption that student SWB is more than simply lining up daily events. A more holistic view on school leads to different (i.e., more positive) results than a focus on singular experiences.

Independent of the method of measurement, the following interindividual differences in student SWB according to achievement, motivation, gender, and age have been empirically confirmed (e.g., Hascher, 2004, 2007; Konu and Lintonen, 2006):

- High achievers feel better in school than low achievers.
- Students with intrinsic motivation report higher SWB than those with extrinsic motivation.
- Girls report higher scores on SWB but are also likely to describe higher scores on negative components like physical complaints, in comparison to boys.
- Students attending lower classes feel better in school than students in higher grades. Toward the end of compulsory education an increase of SWB can be found.

Differences in student SWB cannot be exclusively attributed to individual characteristics. The following learning conditions in terms of school, instruction, and teaching subjects are of relevance as well (e.g., Opdenakker and van Damme, 2000; Van Petegem *et al.*, 2006):

- Schools differ in their level of student SWB indicating the relevance of school culture variables.
- Students report better SWB scores in schools with a higher academic ranking in comparison to schools with a lower academic ranking.
- Higher levels of SWB are reported in lessons with predominant student orientation in comparison to teacher-centered lessons.
- SWB differs across teaching subjects showing that highly selective subjects are more often associated with lower well-being than subjects with lower achievement pressure.

So far, the results refer to student SWB in general. A more detailed view on the various dimensions of SWB shows interesting differences (e.g., Hascher, 2004, 2007; Van Petegem *et al.*, 2007):

- Students report low degrees of physical complaints.
- Equally, the reported amount of social problems is small.
- More frequent are worries in school.
- A lack of enjoyment in school can be found.
- Students' test anxiety correlates negatively with all dimensions of SWB, even with social problems.

Predictors of student well-being

According to the predictors of general SWB, there are many sources of student SWB (see **Figure 1**). Basically,

the fit of individual goals, values, and expectancies with the school situation is crucial for the development of student SWB, that is, the better the fit, the higher the student SWB.

More systematically, predictors of SWB can be divided into three main groups:

1. Student SWB is influenced by conditions in the environment, primarily by school conditions. Not only dissimilarities of school forms but also school-specific variation in terms of action plans in school, school culture, pedagogical orientation, connections of needs and school characteristics, infrastructure, and facilities have an impact on student SWB. Situation-specific classroom factors like the quality of instruction, facilities, participation of all in the classroom, or the fulfillment of basic needs are of comparable importance. Teachers, as well as classmates, play an essential role for student SWB (Hascher, 2003; Van Petegem *et al.*, 2007): the higher the didactical and social competencies of the teachers, the higher the student SWB. In particular, the more positive their attitudes toward school, the higher their enjoyment in school and the better their academic self-concept. In comparison, the higher the achievement stress, the lower the student SWB, specifically, the higher their worries about school, the more frequent their physical complaints. Social discrimination in the classroom or rejection by peers reduces student SWB, that is, increases their social problems in school. Social support, integration into the classroom, and positive interactions during breaks foster student SWB by promoting positive attitudes toward school and students' academic self-concept, and by preventing social problems in the classroom. However, not only experiences in relationship to the school context but also living conditions, family structure, parental academic orientation, and school orientation of friends can influence student SWB (Martin, 2005).

2. Student SWB can be predicted to some degree by personality variables. In addition to gender, exertion readiness, self-efficacy and control beliefs, goal orientation or tolerance to frustration influence student

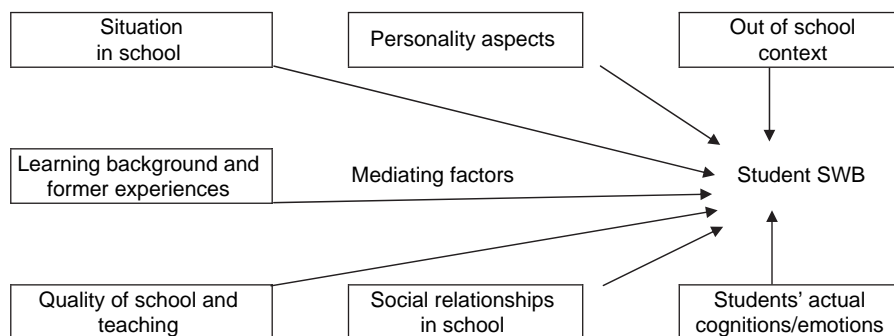

Figure 1 Predictors of student well-being. Hascher, T. (2004). Ein mehrperspektivisches Konzept der Quellen und Bedingungen schulischen Wohlbefindens. In *Wohlbefinden in der Schule (Well-Being in School)*. Münster: Waxmann.

SWB. Gender differences are explained by a gender-specific quality of experiences in that females experience SWB more intensively. There is also a gender-specific way of reporting about emotional experiences, that is, females report about their SWB in a more open way. Exertion readiness, learning orientations, self-efficacy and control beliefs, and tolerance to frustration enable students to manage academic challenges which support success in school. As a consequence, success in school fosters student SWB.

3. Although context and personality variables can influence student SWB directly, most effects result from person–environment interaction. The interaction is represented by subjective differences to how school-related conditions and events are evaluated and interpreted. For instance, different evaluations result from social comparisons, processes of adaptation to the school situation, personal interests, coping with challenging situations, causal attributions, etc. These variables affect how school is perceived, how an individual's situation is related to the context, and they are powerful for students' self-evaluations. They can have a direct impact on student SWB or serve as mediators between school conditions, personality traits, and student SWB.

Teacher well-being

SWB as an indicator of the quality of life is not only important for students but also crucial for teachers' physical functioning and mental health. Till now, however, teacher SWB has not been directly addressed – neither from well-being research nor from research on teachers and teaching. Instead, concepts like life or job satisfaction, intrinsic motivation, flow and emotions at work, or the severe problems of burnout or stress at work are primarily studied as indicators of teacher SWB. Teacher SWB cannot yet be reduced to the existence of job satisfaction or the absence of stress. In future, it has to be studied as a distinct quality.

Job satisfaction is often considered as a valid indicator of SWB at work, although it is frequently defined as a cognitive job attitude, neglecting the emotional dimension of SWB. Moreover, research on job satisfaction shows discrepant results (Bieri, 2006). The majority of teachers are satisfied with their job. However, this is only a limited mirror of their job situation because job satisfaction predicts achievement, burnout, absenteeism, fluctuation, etc., less than what is expected. The clearest differences can be found between teachers experiencing high satisfaction and those experiencing lesser satisfaction: that is, high satisfaction is positively associated with health and negatively with thoughts about job quitting. Low satisfaction goes together with stress and unsuccessful coping strategies.

The subjectively experienced level of stress is high for many teachers despite their positive job satisfaction.

Furthermore, the level of job satisfaction can vary between different areas: for example, teachers are highly satisfied with the content factors (e.g., work with children, instruction, and teaching) but dissatisfied with organizational factors (e.g., classroom size, amount of administrative tasks) and professional support. There are also significant differences in terms of school type, indicating high levels of job satisfaction for nursery and primary school teachers in comparison to secondary school teachers. It must also be noted that relevant sources of job satisfaction (e.g., interaction with students) can at the same time serve as causes for stress. As a result, a more differentiated approach to satisfaction in terms of the quality of experience and the evaluated subject is recommended. For example, different forms of satisfaction can be identified. Some of them result from a negative social comparison or a resigned view on one's own situation. Satisfaction can be experienced, if a person compares his/her situation with others who are in a much worse situation or if they accept the fact that their goals cannot be reached. Thus, individual goals and aspiration levels are crucial variables for the development of job satisfaction.

According to research on general SWB, similar predictors for teacher SWB can be assumed. They can be divided into context factors, personality, and their interplay. Regarding context factors, the workplace is the main context and predictor of SWB. The specific conditions of working in schools and their subjective perception by teachers need to be taken into account, for example, high autonomy of teachers, high responsibility for students' learning outcomes, relatively low support of colleagues, a continuous process of educational top-down reforms, high achievement pressure caused by the curriculum and by school evaluation, the challenging task of handling interruptive student behavior, and so on. Furthermore, a discrimination of intrinsic factors like contribution to children's education and development, and extrinsic factors like salary and social status is helpful.

As a consequence, resources at work are of specific importance (Salanova *et al.*, 2006). Two forms of resources and their interaction can be differentiated: personal resources (e.g., self-efficacy beliefs) and organizational resources (e.g., autonomy and social support at work). Research on personal resources confirms that high levels of self-efficacy beliefs can foster job satisfaction and SWB at work. Similarly, organizational resources have an impact on job satisfaction. Yet, there is no mono-causal relationship; reversed causal relationships are also found, that is, job satisfaction has an influence on future personal and organizational resources.

PREFACE

A preface usually provides a brief introduction to a work, intended to set the stage, provide some background insight, and whet the appetite of the reader. In our case, however, this preface has to address a fundamental question, one that was in our minds at the time we were recruited as Editors-in-Chief for the International Encyclopedia of Education. The question was “Why do we need an Encyclopedia? Its subtext was inspired by the ever-growing, ever-popular Internet. We believe that *this* Encyclopedia is desperately needed and will become a valued resource in education and associated social sciences and arts. The reasons are intellectual and procedural. Anyone with a modicum of knowledge knows that finding and trusting information gleaned from the Internet are two separate actions. The reliance on browsers to help discover references and comments result in resources based on popularity not quality. Pithy titles catch the eye and references rise in the ranks of browser searchers. Related to this is the “editing” in the Internet realm of populist efforts at encyclopedia, references, and other compilations. Once again, after removing offensive material, the accuracy, completeness, lack of bias, and other provenance for entries simply do not exist. Experienced researchers in education can sort through and make intelligent choices. Novices and many journeyman, or practitioners, parents, and policy makers cannot. Contrast how this Encyclopedia was built. Key domains of educational research were identified, and a tentative list of sub-domains or useful applied areas was posited. Then the Editors-in-Chief (apologies for the awkwardness of the term) identified the leading researcher in a particular domain, and with surprisingly little effort, recruited them to participate. They in turn identified the two best researchers in a sub-domain, such as formative assessment or the training of pre-school teachers. The authors of the sections of the Encyclopedia do not represent a collective group of friends and acquaintances, although friendships have been made. Rather they embody a deep and broad scholarly community. The difference from compiled Internet resources is the built-expertise and intellectual engagement of the authors. The summary of the developments and futures in their personal areas of scholarship have been filtered through their years of experience, both as scholars and communicators. Quality, then, is endemic to each piece, developed through this top-down identification of expertise, and made indelible by the bottom-up application of high standards from people leading the sub-domains – the authors, and the domains themselves, the section editors.

On a procedural level, the publishers early committed to the notion that this Encyclopedia would also be an online resource, and access would be available through print, for those with strong bookcases and the persisting love of turning real pages. The Internet version will allow multiple prisms through which the reader may access articles and provide, as it were, an emulation of the Internet in our field, albeit bounded by expertise and high quality.

What must be underscored in the assessment of this effort are the Editors-in-Chief and the publishers’ commitment to find excellence worldwide. We tried very hard to persuade notable scholars from all parts of the world to make contributions. Less than to fulfill the title of “International,” we were on the hunt for perspectives that would enrich the scope and depth of the sections. Our section editors put in enormous time attempting to find the best in the field, wherever they resided. Yet, not everyone is in the volume. Some were overcommitted. Many were not fully confident of their English, and the automated translation software has not yet met standards for technical writing. We believe that such writing and editing tools will make the outreach to an even broader International group of scholars possible in future revisions, or online updates. Furthermore, the birth of the World Educational Research Association (in 2009) will provide a better set of interlocking networks to find and evaluate scholarship from any place on the globe.

Finally, the scope of the effort must be acknowledged: 28 section editors, 926 articles were commissioned, drafted, reviewed, redrafted, edited, and put together in the space of four years. The publishers underwent some internal changes, and alterations in management. We as Editors-in-Chief, changed roles, moved, and also had to keep our own research and development enterprises afloat. Deadlines wobbled; authors dropped from view and had to be replaced.

Yet, at times frustrating as all development is, we find the final product exhilarating. We are enthusiastic not simply because it came into being at all, but because the collective light of the minds that wrote have left a bright resource for the future, one that will impact the way our colleagues understand and experience the educational knowledge, improvement, and impact in the future.

HOW TO USE THE ENCYCLOPEDIA

The International Encyclopedia of Education is intended for use by students, research professionals, and interested others. Articles have been chosen to reflect major disciplines in the study of education and common topics of research by academics in this domain. Each article serves as a comprehensive overview of a given area, providing both breadth of coverage for students, and depth of coverage for research professionals. We have designed the encyclopedia with the following features for maximum accessibility for all readers.

The contents of the encyclopedia are arranged alphabetically by section, and within sections, alphabetically by article. The Subject Index is located in Volume 8. Some topics are covered in a multitude of articles from differing perspectives, while other topics may have only one entry. We encourage use of the index for access to a subject area, rather than use of the Contents list alone, so that a reader has a full notion of the coverage of that topic.

The articles include cross-references to other related encyclopedia articles, suggested further readings where applicable, and many contain relevant websites for additional information. We encourage readers to use the cross-references to locate other encyclopedia articles that will provide more detailed information about a subject.

The Further Reading sections include recent secondary sources to aid the reader in locating more detailed or technical information. Review articles and research articles that are considered of primary importance to the understanding of a given subject area are also listed. These suggested further readings are not intended to provide a full reference listing of all material covered in the context of a given article, but are provided as next steps for a reader looking for additional information.

VOLUME 1

A

Adult Education

Adult Education Overview	<i>K Rubenson</i>	1
--------------------------	-------------------	---

Adult Education – Adult Learning, Instruction and Program Planning

Adult Learning	<i>S B Merriam</i>	12
Adult Learning and Instruction: Transformative Learning Perspectives	<i>P Cranton</i>	18
Adult Learning in a Biographic Perspective	<i>L West</i>	25
Adult Learning, Instruction and Programme Planning: Insights from Freire	<i>P Mayo</i>	31
Characteristics of Adult Learning	<i>K Illeris</i>	36
Informal Learning: A Contested Concept	<i>P Hodgkinson</i>	42
Organizational Learning	<i>P-E Ellström</i>	47
Program Planning	<i>A L Wilson and R M Cervero</i>	53
Workplace Learning Frameworks	<i>S Billett</i>	58

Adult Education – as a Field of Study

Class Analysis in Adult Education	<i>T Nesbit</i>	64
Gender Analysis	<i>J Stalker</i>	70
Race and Ethnicity in the Field of Adult Education	<i>J Johnson-Bailey and D Drake-Clark</i>	77
Trends in Workplace Learning Research	<i>T Fenwick</i>	83

Adult Education – Concepts

Lifelong Learning	<i>J Field</i>	89
Rewriting the History of Adult Education: The Search for Narrative Structures	<i>B J Hake</i>	96

Adult Education – Domains and Provision

Adult Basic Education: A Challenge for Vocational Based Learning	<i>R Höghelm</i>	102
Adult Literacy Education	<i>L Tett and R St.Clair</i>	107
Citizenship and Immigrant Education	<i>D Schugurensky</i>	113
Community Based Adult Education	<i>B Connolly</i>	120
Continuing Professional Education: Multiple Stakeholders and Agendas	<i>R M Cervero and B J Daley</i>	127
Financing of Adult and Lifelong Learning	<i>Å Sohlman</i>	133
Labor Education	<i>K Forrester</i>	139
Learning Cities and Regions	<i>C Duke</i>	144
Museums as Sites of Adult Learning	<i>R S Grenier</i>	150
Overview of Lifelong Learning Policies and Systems	<i>D-B Kwon and C H O Daeyeon</i>	156
Popular Adult Education	<i>S Tøsse</i>	162
Provision of Prior Learning Assessment	<i>P Andersson</i>	169
The Age of Learning: Seniors Learning	<i>P Jarvis</i>	175
University Adult Continuing Education: The Extra-Mural Tradition Revisited	<i>M Slowey</i>	183

Adult Education – Economy and Society

Adult Education and Civil Society	<i>J Crowther and I Martin</i>	191
Adult Education and Nation-Building	<i>S Walters</i>	198
Economic Outcomes of Adult Education and Training	<i>A Ferrer and W C Riddell</i>	204
Health and Adult Learning	<i>P Bélanger and M Robitaille</i>	211
Modernization Processes and the Changing Function of Adult Learning	<i>H S Olesen</i>	217
The Political Economy of Adult Education	<i>G Rees</i>	223
Wider Benefits of Adult Education	<i>R Desjardins and T Schuller</i>	229

Adult Education – Participation

Barriers to Participation in Adult Education	<i>K Rubenson</i>	234
Participation in Adult Learning	<i>R Desjardins</i>	240

C**Comparative Education**

Comparative and International Education: English-Language Scholarly Publications	<i>D Post and M Fedri</i>	251
Comparative Education: Philosophical Issues and Concepts	<i>M Mason and C W Evers</i>	257
Comparative Education: Societies and Associations	<i>M Bray</i>	266

Curriculum Development

Curriculum and Religion	<i>C Kapitzke and P Graham</i>	272
Gender and Curriculum	<i>J Marsh</i>	277
Local Teacher-Based Curriculum Development	<i>M D Osborne and H B Barker</i>	283

Curriculum Development – Contexts

Curriculum and Human Rights	<i>C Lohrenscheit</i>	287
Curriculum and the Education of Cultural and Linguistic Minorities	<i>S May</i>	293
Curriculum in Postcolonial Contexts	<i>A Hickling-Hudson</i>	299
Curriculum, Economic and Cultural Development	<i>A Rampal</i>	307
Globalization and Curriculum	<i>R Dale</i>	312
Popular Culture	<i>K Schultz and R Throop</i>	318

Curriculum Development – Evaluation and Research

An Overview of Research in Curriculum Inquiry	<i>F M Connelly and S J Xu</i>	324
Curriculum Evaluation: Approaches and Methodologies	<i>V Klenowski</i>	335
Curriculum Studies, Discourse Analysis, and the Construction of Historical Time	<i>J Laspina</i>	342
Curriculum Use in the Classroom	<i>M Ben-Peretz and B Eilam</i>	348
The Roots and Routes of Teacher-Based Action Research and Curriculum Inquiry: An Historical Perspective	<i>L G Putney and J L Green</i>	355

Curriculum Development – Planning and Development

Curriculum and Syllabus Design	<i>A Woods, A Luke, and K Weir</i>	362
Curriculum and the Publishing Industry	<i>J Larson, A-R Allen, and D Osborn</i>	368
Curriculum and Teacher Change	<i>J G Ladwig</i>	374
Curriculum Governance and Planning	<i>B Levin</i>	379
Curriculum Planning and Systems Change	<i>Z Deng</i>	384
Curriculum, Digital Resources and Delivery	<i>Y Zhao, G Zhang, and C Lai</i>	390
Textbook Development and Selection	<i>P Shannon</i>	397

Curriculum Development – Subject Matter

Curriculum and Globalization: Higher Education	<i>K H Mok</i>	403
Curriculum Development as Subject Matter: Social Studies	<i>J Brophy and J Alleman</i>	411
Curriculum Development in the Area of Reading	<i>C L Madda and T E Raphael</i>	415
Curriculum in the Arts	<i>C M Thompson, L Bresler, and T E Costantino</i>	423
Curriculum: Foreign Language Learning	<i>Angel M Y Lin</i>	428
First Language Learning	<i>T Rogers and L Moffatt</i>	435
Learning a Second Language in First Language Environments	<i>E Bernhardt and D J Tedick</i>	441
Literature	<i>S Hynds</i>	447
Mathematics	<i>B Kaur and C P Vistro-Yu</i>	453
Physical Education and Sports	<i>D Kirk</i>	459
Primary and Elementary/Middle Grades Reading	<i>D E Alvermann and C A Mallozzi</i>	464
Science	<i>Y Kali and M Linn</i>	468

Curriculum Development – Theory

Bilingual Learning (Learning L1 and L2 in an L1 and L2 Environment)	<i>D Schwinge</i>	475
Curriculum and Complex Systems Theory	<i>W-M Roth and J Thom</i>	481

Curriculum and Constructivism	<i>B Davis and D Sumara</i>	488
Curriculum and Critical Theory	<i>L Yates</i>	494
Curriculum and Poststructuralist Theory	<i>J L Miller</i>	499
Curriculum and Structuralist Sociology: The Theory of Codes and Knowledge Structures	<i>J Muller and J Gamble</i>	505
Curriculum Reform	<i>R Gilbert</i>	510
Early Childhood Curriculum and Developmental Theory	<i>S M-Y Lim and C Genishi</i>	514

D

Demography and Social Change

An Evaluation Framework for E-Learning Effectiveness in the Arab World	<i>W AbuSneineh and M Zairi</i>	521
Globalization and Social Justice in Higher Education	<i>E Kimura-Walsh</i>	536
Racial Inequality and the Economic Payoffs of Higher Education	<i>S A Lachtman</i>	542
School Health Education	<i>J S Yang</i>	547

Demography and Social Change – Demography

A Paradigm of Contradictions: Racism and Science Education	<i>B A Brown and J W Mutegi</i>	554
Africana Studies: Past, Present And Future	<i>B R Hare, A Young, J B Stewart, and D P Aldridge</i>	565
Beyond Black Nationalism to Black Internationalism: The Compelling Case for Examining Black Educational Challenges Globally	<i>K Freeman</i>	573
Beyond Racial, Ethnic, and Gender Bias in Education Statistics	<i>J T Lott and C Bennett</i>	581
Caste and Education in India	<i>G G Wankhede</i>	589
Demography, Community, and the Education of Asian American and Pacific Islander Students	<i>R T Teranishi</i>	595
Educational Attainment and Mortality Differentials	<i>H D Horton, L Hixson, and S M Monnat</i>	602
Educational Opportunity and Latino/Chicano College Choice: New Findings, and Theoretical Perspectives	<i>M A Ceja and P A Pérez</i>	610
Ethnic Minority Identity and Educational Outcomes in a Rising China	<i>G A Postiglione</i>	616
Ethnic Studies and Women's Studies: From the Past to the Present, Providing a Space in the Academy for Scholarship Focused on the Histories and Experiences of Marginalized People	<i>C A Brown</i>	623
Gender Equity in Higher Education: Challenges and Celebrations	<i>L Morley</i>	629
Locating Space and Place in the College Access Debate: New Tools for Mapping and Understanding Educational Inequity and Stratification	<i>B Cantwell and J F Milem</i>	636
Public Policy and Inequality in Postsecondary Opportunity: Educational Statistics and the Failure of Education Reform	<i>E P St. John, K Williams, and K Moronski</i>	649
The Education of Indigenous Students	<i>J W Tippeconnic and S C Faircloth</i>	661

Scholar-Baller®: Student Athlete Socialization, Motivation and Academic Performance in American Society	<i>C K Harrison, S Bukstein, J Mottley, E Comeaux, J Boyd, C Parks, and D Heikkinen</i>	860
Service-Learning and Diversity as Mediums to Foster Civic and Community Engagement in Undergraduates	<i>L Oseguera</i>	866
Success and Failure in Education and Criminal Justice: Identifying Common Mechanisms	<i>S Ramirez and A Harris</i>	874
The History of Education: Race and Education	<i>J O Jewell</i>	881

VOLUME 2**E****Early Childhood Care and Education Theory**

- Early Childhood Care and Education: The Family, The Market, and The State *S B Kamerman and M J Neuman* 1
- Gender Issues in Early Childhood Education and Care *B Pocock* 11

Early Childhood Education and Care Governance

- Early Childhood Risk, Protection and Abuse Prevention *E Khoo* 17
- Evaluating Early Childhood Education and Care Programs *M Janus and S Brinkman* 25

Early Childhood Education and Care Investment

- Investing in Early Childhood Education and Care: The Health and Wellbeing Case *T Moore and F Oberklaid* 32
- Cost-effective Early Childhood Programs from Preschool to Third Grade *A J Reynolds, J A Temple, and B White* 38
- Early Childhood in Post-Modern Cultures: Thoughts and Some Concerns *P Gammage* 49
- Investing in Early Childhood Education and Care: Some Policy Implications *J Bennett* 55
- Investing in Early Childhood Education and Care: The Economic Case *G Cleveland and M Krashinsky* 63

Early Childhood Education and Care Programs

- Early Care and Education Programs for Infants and Toddlers *B Nyland* 69
- Literacies in Early Childhood: The Preschool Period *M Fleeer and B Raban* 75
- Participation in Early Childhood Education and Care Programs: Equity, Diversity and Educational Disadvantage *M Vandenbroeck* 81
- Teaching in Early Childhood Centers Instructional Methods and Child Outcomes *I Siraj-Blatchford* 86

Early Childhood Education and Care Provision

- Early Childhood Education and Care in the People's Republic of China *Zeng Xiaodong* 93
- Home-Based and Institutional Early-Childhood Education and Care Services *R Fukkink and H Blok* 98
- Integrated Early Childhood Education and Care Services – Care, Upbringing, Education and Health *S Colley* 104
- Issues of Access and Program Quality *J T Hustedt and W S Barnett* 110
- Kindergarten Transitions and Linkages to Primary School – Readiness Re-conceptualized *A Petriwskyj* 120
- Parent Support in Early Childhood – Approaches and Outcomes *K S Howard, K A Beckmann, and J Brooks-Gunn* 126

Early Childhood Education and Care Research

- Development and Implementation of Early Learning Standards in the United States *C Scott-Little* 132
- Global Status of Early Learning and Development Standards *P R Britto and S L Kagan* 138
- Rethinking Early Childhood Education and Care: Implications for Research and Evaluation *K Thorpe, D Cloney, and C Tayler* 144

Early Childhood Education and Care Theory

- Child Rearing and Early Education: Parents and Professionals: Theoretical and Historical Influences *H Penn* 151

Early Childhood Education and Care Workforce

- Early Childhood Education and Care Professional Profiles in the United Kingdom: Multiagency Teamwork and Transdisciplinary Challenges *A Anning and P Calder* 157
- Early Childhood Education and Care Staff Support: Mentoring and Professional Development in Finland *P Lindberg* 162

Economics of Education

- Education and Health *P Muennig* 169
- Data *M Perez and M Socias* 178
- Empirical Research Methods in the Economics of Education *P J McEwan* 187
- Theoretical Concepts in the Economics of Education *D J Brewer, G C Hentschke, and E R Eide* 193

Economics of Education – Costs and Financing of Schooling

- Cost–Benefit Analysis and Cost–Effectiveness Analysis *C Belfield and H M Levin* 199
- Economic Approaches to Adequacy *J Imazeki* 204
- Economic Approaches to School Efficiency *L L Taylor* 210
- School Finance Reform *T Downes* 216
- School Finance: An Overview *J K Rice, D H Monk, and J Zhang* 222
- The Economics of Tuition and Fees in Higher Education *R G Ehrenberg* 229

Economics of Education – External Benefits of Schooling

- Education and Civic Engagement *T S Dee* 235
- Education and Crime *L Lochner* 239
- Education and Economic Growth *E A Hanushek and L Wößmann* 245
- Parental Socioeconomic Status, Child Health, and Human Capital *J Currie and J Goodman* 253
- The External Benefits of Education *W W McMahon* 260

Economics of Education – Labor Markets, Education and Earnings

- Education and Inequality *J Blanden and S Machin* 272
- Human Capital *E R Eide and M H Showalter* 282
- Race Earnings Differentials *M Carnoy* 288
- Returns to Education in Developed Countries *M Gunderson and P Oreopoulos* 298
- Returns to Education in Developing Countries *H A Patrinos and G Psacharopoulos* 305
- School Quality and Earnings *J R Betts* 313
- Signaling in the Labor Market *M E Page* 321
- The Economics of High School Dropouts *R W Rumberger* 325

Economics of Education – Markets, Incentives and School Choice

- Competition and Student Performance *A A Payne* 331
- Educational Privatization *C Belfield and H M Levin* 337

Student Incentives	<i>E R Eide and M H Showalter</i>	342
The Economic Role of the State in Education	<i>D N Plank and T E Davis</i>	347
The Economics of Catholic Schools	<i>W Sander and D Cohen-Zada</i>	354
The Economics of Charter Schools	<i>R Zimmer and R Buddin</i>	360
The Economics of Parental Choice	<i>R Chakrabarti and J Roy</i>	367
The Economics of School Accountability	<i>D N Figlio and H F Ladd</i>	374
The Efficacy of Educational Vouchers	<i>R Zimmer and E P Bettinger</i>	380
Tiebout Sorting and Competition	<i>T J Nechyba</i>	388

Economics of Education – Production of Schooling

Desegregation, Academic Achievement and Earnings	<i>S Rivkin</i>	394
Education Production Functions: Concepts	<i>D N Harris</i>	402
Education Production Functions: Developed Country Evidence	<i>E A Hanushek</i>	407
Education Production Functions: Evidence from Developing Countries	<i>P Glewwe and S Lambert</i>	412
Family Environment in the Production of Schooling	<i>R Rothstein</i>	423
Neighborhoods and Peers in the Production of Schooling	<i>J Vigdor and J Ludwig</i>	431
Teacher Quality in Education Production	<i>I Pelayo and D J Brewer</i>	438
The Economics of Class Size	<i>D W Schanzenbach</i>	443
The Economics of Early Childhood Interventions	<i>M Nores</i>	450

Economics of Education – Teaching Labor Markets

An Overview of Teacher Labor Markets	<i>H Lankford and J Wyckoff</i>	456
Compensating Differentials in Teacher Labor Markets	<i>J Chambers</i>	465
Economic Approaches to Teacher Recruitment and Retention	<i>S Loeb and J Myung</i>	473
Teacher Incentives	<i>L Santibañez</i>	481
Teacher Supply	<i>P Dolton</i>	489
Teacher Training and Preparation in the United States	<i>M Podgursky, M G Springer, and R Hutton</i>	498
Teachers in Developing Countries	<i>F H Rogers and E Vegas</i>	504
The Economics of Teachers' Unions in the United States	<i>K Strunk</i>	512

Education of Children with Special Needs

Adapted Physical Activity for Students with Special Needs	<i>S R Hodge</i>	519
Assessment Accommodations for Children with Special Needs	<i>R J Kettler and S N Elliott</i>	530
Assistive Technology and Educational Practice	<i>H P Parette and G R Peterson-Karlan</i>	537
Augmentative–Alternative Communication	<i>C Mason and K M Chinn</i>	544
Community Integration and Employment of Youth with Special Needs	<i>B A Ford and A W Daviso III</i>	550
Cooperative Learning for Children with Special Needs	<i>E A Dooley and K R Kossar</i>	555
Co-Teaching	<i>E D Cramer</i>	560
Cultural and Linguistic Diversity and Children with Special Needs	<i>J M Patton, N Day-Vines, and A McSwain</i>	565
Curriculum-Based Assessment and Students with Special Needs	<i>D J O'Shea and J D Katsafanas</i>	571

Diagnosis and Classification	<i>M Sapp</i>	577
Direct Instruction and the Education of Children with Special Needs	<i>T Mehring</i>	584
Disabilities and Gifted Education	<i>V I Daniels and M J McCollin</i>	588
Early Childhood Special Education: Birth to Eight Years Old	<i>T S Lovelace, R Gardner III, J B Axe, and D M Sainato</i>	594
Early Intervention for Students with Special Needs	<i>P A Grant</i>	608
Early Transition of Children with Special Needs	<i>S A Fowler</i>	613
Educating Children Who are Deaf-Blind	<i>J Wood and K M Chinn</i>	621
Educating Children with Deafness and Hearing Impairments	<i>G M Mukuria and C J Eleweke</i>	628
Educating Children with Other Health Impairments (ADHD)	<i>G M Mukuria and F E Obiakor</i>	634
Educating Children with Physical Disabilities	<i>Z P Nkabinde, F E Obiakor, M T Ofor, and D J Smith</i>	640
Educating Children with Specific Learning Disabilities	<i>P A Grant and P B Grant</i>	646
Educating Children with Speech and Language Disorders	<i>S L Green and C D Qualls</i>	654
Educating Students with Autism and Related Disorders	<i>T T Dyches</i>	661
Educating Students with Cognitive Disabilities	<i>J P Bakken</i>	669
Educating Students with Emotional and Behavioral Disorders	<i>S W Smith and G G Taylor</i>	678
Educating Students with Special Needs: An Overview	<i>F E Obiakor, M K Harris, P Harris-Obiakor, and G M Mukuria</i>	688
Educating Students with Traumatic Brain Injury	<i>S Burkhardt and A Rotatori</i>	695
English Language Learners with Special Needs	<i>R Rueda and G Ragusa</i>	701
Functional Behavioral Assessment	<i>J P Bakken</i>	708
History of Special Education	<i>L M Garrick Duhaney and S J Salend</i>	714
Inclusion of Students with Special Needs in General Education Classrooms	<i>M A Prater</i>	721
Instructional Accommodations for Children with Special Needs in Inclusive Settings	<i>A L Yurick, S Musti-Rao, and G Cartledge</i>	727
Interagency Agreements	<i>L A Owens</i>	733
Interdisciplinary Collaboration in Early Childhood	<i>N File</i>	739
Language Development in Children with Special Needs	<i>M S L Stewart</i>	745
Large Scale Assessment and Accountability and Students with Special Needs	<i>M L Thurlow</i>	752
Literacy Instruction for Students with Special Needs	<i>L H Mason</i>	759
Math Instruction for Children with Special Needs	<i>B A Bottge</i>	767
Overrepresentation of Culturally and Linguistically Diverse Students in Special Education	<i>S C Trent</i>	774
Paraprofessionals in Special Education	<i>B Y Ashbaker, S C Dunn, and J Morgan</i>	780
Parent and Family Involvement in the Education of Children with Special Needs	<i>L P Prater</i>	788
Peer Relations and Socialization of Children and Adolescents with Special Needs	<i>L M Bullock, M Wong-Lo, and R A Gable</i>	794
Peer-Tutoring	<i>L J O'Shea and D J O'Shea</i>	802
Postsecondary Participation of Students with Special Needs	<i>R A Stodden and K D Roberts</i>	808
Prereferral Strategies	<i>C G Simpson and J P Bakken</i>	815

Preventing Antisocial Behavior and Delinquency: A Comprehensive School-wide Approach <i>P R Hallam, K R Young, P Caldarella, D G Wall, and L Christensen</i>	820
Programs and Instructional Strategies for Students with Gifts and Talents <i>V I Daniels and M J McCollin</i>	829
Related Services for Children with Special Needs <i>S O Obi</i>	834
Risk and Resilience Frameworks in Understanding Special Education <i>W-Y Hsieh and M L Donahue</i>	840
School Dropout Prevention <i>F E Obiakor</i>	845
School-Based Services for Children with Special Needs <i>S O Obi</i>	850
Self-Determination <i>M L Wehmeyer</i>	857
Social Competence <i>L A Owens and S Johnston-Rodriguez</i>	865
The Identification of Students with Gifts and Talents <i>V I Daniels and M J McCollin</i>	870
Transition from School to Adult Life <i>M J McCollin and F E Obiakor</i>	876
Visual Impairment <i>W Sapp</i>	880
Workforce Issues in Special Education <i>E Carlson and B Billingsley</i>	886

VOLUME 3

Education of Professionals

An Overview of Accreditation, Certification, and Licensure Processes <i>J J Norcini and M van Zanten</i>	1
Educating America's Military Officers <i>M H Adamshick</i>	7
Education for Architecture in the United States and Canada <i>S Schreiber</i>	13
Education for Medicine <i>M B Anderson</i>	19
Education for the Legal Profession <i>J W Wegner</i>	25
Education of Clergy <i>D O Aleshire</i>	31
Framing Professions Education <i>P S O'Sullivan</i>	37
Issues in Accounting/Business Education <i>W H Gijsselaers and R G Milter</i>	39
Professions – Engineering <i>J Heywood</i>	45
Professions – Health-Related <i>G M Jensen and C B Royeen</i>	51
Professions – Pharmacy <i>D E Beck</i>	58
Teaching for the Complex Practice of Nursing <i>P Benner and M Sutphen</i>	65
Veterinary Education <i>K M Edmondson</i>	71

Education Research Methodology: Quantitative Methods and Research

Abductive Research Methods <i>B D Haig</i>	77
Field Experimentation in Education <i>M A Constan</i>	83
Internal Validity <i>M H Clark and S C Middleton</i>	90
Methods for Approximating Random Assignment <i>B Schneider and S-K McDonald</i>	97
Methods for Approximating Random Assignment: Regression Discontinuity and Propensity Scores <i>L M Scheier</i>	104

Multitrait–Multimethod Designs	<i>M Bong and S Hong</i>	111
Multivariate Longitudinal Data Analysis	<i>H Liu and L Chang</i>	120
Quasi-Experimentation: Two Group Design	<i>E Hong</i>	128
Regression Discontinuity Designs	<i>A Kelava, S Rohrmann, and V Hodapp</i>	134
Sampling	<i>R S Brown</i>	142
Statistical Conclusion Validity	<i>P L Busk</i>	147
Survey Research Methods	<i>A Fink</i>	152

Educational Assessment

An Overview of Educational Assessment	<i>M James</i>	161
Assessment and the Evaluation of Institutional Effectiveness	<i>S M Thomas</i>	172
Assessment in Schools – Dispositions	<i>R D Crick</i>	181
Assessment in Schools Related To Literacy: Reading	<i>K J Topping</i>	189
Impact of Assessment on Students' Learning Strategies and Implications for Judging Assessment Quality	<i>M Segers, F Dochy, and D Gijbels</i>	196

Educational Assessment – Assessment Activities

Alternative Assessment	<i>G Stobart and C Gipps</i>	202
Classroom Assessment Tasks and Tests	<i>J Phelan and J Phelan</i>	209
Dynamic Assessment	<i>J G Elliott, E L Grigorenko, and W C M Resing</i>	220
Instructional System Provided Feedback	<i>H F O'Neil, S Chuang, and T Huang</i>	226
Peer and Self-assessment	<i>C Harrison</i>	231
Portfolio Assessment	<i>V Klenowski</i>	236
Records of Achievement: Beyond Traditional Tests	<i>P Broadfoot</i>	243

Educational Assessment – Assessment in Domains

Assessment in Higher Education	<i>D R Sadler</i>	249
Assessment in Schools – Affective Domain	<i>M Ventura, R D Roberts, and M Zeidner</i>	256
Assessment in Schools – Creative Subjects	<i>T E Costantino and L Bresler</i>	262
Assessment in Schools – Learning to Learn	<i>A Hautamäki, J Hautamäki, and S Kupiainen</i>	268
Assessment in Schools – Literacy Writing (Extended)	<i>J M Parr and L Earl</i>	273
Assessment in Schools – Mathematics	<i>M Brown and J Hodgen</i>	279
Assessment in Schools – Oracy	<i>A L Bailey</i>	285
Assessment in Schools – Primary Science	<i>W Harlen</i>	293
Assessment in Schools – Secondary Science	<i>J Shemwell, A Fu, M Figueroa, R Davis, and R Shavelson</i>	300
Assessment in Schools – Technology Education and ICT	<i>A Jones, B Cowie, and J Moreland</i>	311
Assessment in the Early Years	<i>M J Drummond</i>	316
Assessment in the History, Civics and Social Studies Domains	<i>P G Avery</i>	323
Assessment in the Workplace of Performance, Developing Expertise and Competence	<i>A J Brown</i>	330
Assessment in Vocational Education	<i>K Ecclestone</i>	337

Educational Assessment – Concepts and Issues

Assessing Group Work	<i>M Galton</i>	342
Assessment and the Regulation of Learning	<i>L Allal</i>	348
Challenges of Developing and Implementing Formative Assessment Practices in Schools	<i>R Sutton</i>	353
Formative Assessment	<i>P Black</i>	359
Formative Assessment and Instructional Planning	<i>B Marshall</i>	365
Progression and Assessment: Developmental Assessment	<i>M Forster and G Masters</i>	369
Students' Rights in Assessment and Evaluation	<i>J Gardner and B Holmes</i>	378
Summative Assessment by Teachers	<i>R Daugherty</i>	384
The Multiple Purposes of Assessment	<i>P E Newton</i>	392
The Relationship between Assessment and the Organization and Practice of Teaching	<i>L B Resnick, D William, R Apodaca, and E S Rangel</i>	397

Educational Assessment – Enhancing Quality and Use

Assessment Conversations: Reading and Writing Conferences with Students and with Parents	<i>M Barrs</i>	403
Assessment: Pre-service and In-service Teacher Education	<i>A Davies</i>	410
Classroom Assessment in Policy Context (Australia)	<i>J J Cumming</i>	417
Classroom Assessment in Policy Context (England and France)	<i>M Osborn and M Raveaud</i>	425
Classroom Assessment in Policy Context (French Sources)	<i>D Laveault</i>	432
Classroom Assessment in Policy Context (Hong Kong)	<i>D Carless</i>	438
Classroom Assessment in Policy Context (New Zealand)	<i>T J Crooks</i>	443
Classroom Assessment in Policy Context (Sub-Saharan Africa)	<i>S J Howie, L Zimmerman, and K Draper</i>	449
Moderation of Student Work by Teachers	<i>G S Maxwell</i>	457
School Policies and Practices to Support Effective Classroom Assessment for Learning	<i>D Pedder</i>	464
Student Assessment: Policy and Practice in Eastern Europe	<i>G Bethell</i>	472

Educational Assessment – Key Relationships

Assessment Practice in Policy Context: Latin American Countries	<i>F M Rizo</i>	479
Impact of Assessment on Learner Groups (Boys/Girls)	<i>J Elwood</i>	486
Impact of Assessment on Learner Groups (Disabilities)	<i>M Rouse</i>	492
Impact of Assessment on Students' Test Anxiety	<i>P Buchwald and C Schwarzer</i>	498
Impact of Assessments on Classroom Practice	<i>J L Herman</i>	506
Social Practices in School Assessment and their Impact on Learner Identities	<i>A Pollard and A Filer</i>	512

Educational Evaluation – Concepts, Practice, and Future Directions

Educational Evaluation: Concepts, Practice, and Future Directions	<i>Y J Ni</i>	518
---	---------------	-----

Educational Evaluation – Contemporary Themes in Evaluation

Evaluating E-Learning	<i>D D Williams and C R Graham</i>	530
Evaluating Schools as Learning Communities	<i>S M Thomas</i>	539
Evaluation of Adult Education and Training Programs	<i>G McNamara, P Joyce, and J O'Hara</i>	548
Evaluation of Integrated Health Programs in School	<i>T M Franke</i>	555

Formative Assessment in Teacher Education and Teacher Professional Development	<i>H Tillema</i>	563
Informal Education and Evaluation	<i>T Jeffs</i>	572
Methods to Evaluate Technology	<i>W L Bewley</i>	578

Educational Evaluation – Contexts of Educational Evaluation

Cost Analysis in Evaluation Studies	<i>J D Fletcher</i>	585
Cultural Issues that Can Affect the Validity of Educational Evaluations	<i>R P Durán</i>	592
Evaluation and Accountability	<i>E Sato and S N Rabinowitz</i>	600
Evaluation Governance and Planning	<i>R Picciotto</i>	607
Evaluation Use	<i>V G Thomas</i>	614
Moral and Ethical Issues in Evaluation	<i>M Morris</i>	622
The Role of Stakeholders in Educational Evaluation	<i>S Taut and M C Alkin</i>	629

Educational Evaluation – Evaluation Domains

Curriculum Evaluation	<i>T Levin</i>	636
Evaluating Education in Three Policy Eras	<i>M A Peters, R Britez, and S M Weber</i>	645
Evaluation of Mathematics Education Programs	<i>J Cai</i>	653
Evaluation of Science Education Programs	<i>G Berberoğlu</i>	660
Evaluation of Social Studies and Civic Education Programs	<i>S G Grant</i>	667
Evaluation of Teacher Quality and Practice	<i>W Robinson and J Campbell</i>	674
International Evaluations	<i>A Schleicher</i>	681
National Assessment Programs: The Example of the U.S. National Assessment of Educational Progress	<i>M Schneider</i>	690
Principal Evaluation: Concepts, Needs and Realities	<i>N S Glasman and L D Glasman</i>	698
Program Evaluation	<i>C A Christie and L A Fierro</i>	706
School Based Evaluation: Purposes, Protocols and Processes	<i>J MacBeath</i>	713
School Inspection/External School Evaluation	<i>C Chapman and P Earley</i>	719
The International System for Teacher Observation and Feedback: A Theoretical Framework for Developing International Instruments	<i>L Kyriakides, B P M Creemers, C Teddlie, and D Muijs</i>	726

Educational Evaluation – Evaluation Methods

Evaluation Methodology	<i>M Chatterji</i>	735
Evaluation Reporting and Communicating	<i>R T Torres</i>	746
Longitudinal Evaluation Designs	<i>X Ma</i>	757
Meta-evaluation: Purpose, Prescription, and Practice	<i>L A Wingate</i>	765

Educational Evaluation – Purposes and Models of Educational Evaluation

Defining Quality in Evaluation	<i>P Dahler-Larsen</i>	775
Internal and External Evaluation	<i>D Nevo</i>	781
Needs Assessment in Education	<i>J W Altschuld and T L Lepicki</i>	786
The Purpose of Educational Evaluation	<i>S Mathison</i>	792
Understanding Approaches to Evaluation	<i>A J Love</i>	798

VOLUME 4**Educational Measurement**

Ability Testing	<i>P B Tymms</i>	1
Admissions Testing	<i>R Zwick</i>	7
Appropriateness Measurement: Person Fit	<i>R R Meijer and A M Weekers</i>	15
Automated Essay Scoring: Writing Assessment and Instruction	<i>M D Shermis, J Burstein, D Higgins, and K Zechner</i>	20
Classical Test Theory Reliability	<i>M D Miller</i>	27
Criterion-Referenced Measurement	<i>S A Shrock and W C Coscarelli</i>	31
Differential Item Functioning	<i>M D Hidalgo and J Gómez-Benito</i>	36
Educational Measurement: Overview	<i>R L Linn</i>	45
Equating and Scaling	<i>A A von Davier</i>	50
Fairness	<i>C Gipps and G Stobart</i>	56
Generalizability Theory	<i>R L Brennan</i>	61
Impact of Assessment on Classroom Practice	<i>J L Herman</i>	69
Intelligent Systems	<i>V J Shute and D Zapata-Rivera</i>	75
Item Response Theory	<i>W J van der Linden</i>	81
National Assessments	<i>T J Crooks</i>	89
Norm-Referenced Measurement	<i>H D Hoover</i>	95
Progress Monitoring	<i>L S Fuchs and D Fuchs</i>	102
Rasch Models	<i>D Andrich</i>	111
Scoring Rubrics	<i>J A Arter</i>	123
Second Language Assessment	<i>L F Bachman</i>	140
Self Adaptive Testing	<i>J Revuelta</i>	148
Student Test Results in School Accountability	<i>L S Hamilton</i>	153
Test Development	<i>S M Downing</i>	159
Test Translation and Adaptation	<i>A Allalouf and P Hanani</i>	166
Testing Creativity	<i>M A Runco</i>	170
Testing in History	<i>S Wineburg and B Fogo</i>	175
Validity	<i>R L Linn</i>	181
Validity of Achievement Gains on High-Stakes Tests	<i>D Koretz</i>	186
Validity of Educational Indicators	<i>B P M Creemers and L Kyriakides</i>	193

G**Globalization of Universities and Institutions**

Globalization, Universities and Medium of Instruction	<i>J Lo Bianco</i>	201
The Washington Accord on Engineering Curriculum	<i>E Ko</i>	209

H

Higher Education

Higher Education: An Overview	<i>P Scott</i>	217
-------------------------------	----------------	-----

Higher Education – Management, Leadership and Governance

Academic Managers – Heads of Departments/Schools	<i>S Marshall</i>	229
Leading and Managing the University – Presidents and their Senior Management Team	<i>R Middlehurst, T Kennie, and S Woodfield</i>	238
Management of and in Higher Education Institutions	<i>B Sporn</i>	245
Managerialism and Collegialism in Higher Education Institutions	<i>M Shattock</i>	251
Strategic Planning in Higher Education	<i>L Zechlin</i>	256
The Changing Role of University Presidents, Vice-Chancellors and Rectors	<i>M F Green and P D Eckel</i>	264
The Changing Roles of University Governing Boards and Councils	<i>J Fielden</i>	273

Higher Education – Research and Scholarship

Funding of University Research	<i>G Harman</i>	279
Mobility of PhD Students and Scientists	<i>S Avveduto</i>	286
National Science Policy and Universities	<i>M Henkel and U Kogan</i>	294
Research Commercialization	<i>S Slaughter</i>	300
Research Quality Assessment	<i>I McNay</i>	307
The Management of University Research	<i>J Kirkland</i>	316
The Training of New Scientists	<i>R Neumann</i>	322

Higher Education – Society

Academic Freedom	<i>S F Macintyre</i>	328
Access and Equity in Higher Education	<i>G Baldwin and R James</i>	334
Boundaries of Institutional Autonomy and their Impact on Higher Education	<i>V L Meek</i>	341
Diversity of Higher Education	<i>U Teichler</i>	347
Employability of University Graduates and Graduate Outcomes	<i>J Brennan</i>	354
Higher Education and the Knowledge Society	<i>J Välimaa</i>	360
Higher Education and the Labor Market	<i>J Enders</i>	365
Higher Education and the Transformation of Society	<i>P Scott</i>	370
Quality Assurance in Higher Education – Practices and Issues	<i>D Dill</i>	377
The Role of Accreditation of Higher Education Institutions	<i>J S Eaton</i>	384
Universities and Regional Development	<i>J Goddard and J Puukka</i>	390
Universities' Engagement with Society	<i>D Watson</i>	398

Higher Education – Teaching and Learning in Higher Education

Distance Education and Open Universities	<i>A Kanwar and J Daniel</i>	404
Education Development in Higher Education	<i>Y Ryan and K Fraser</i>	411
Effective Use of Technology in Teaching and Learning in HE	<i>D Laurillard</i>	419

Facilitating Students' Success – Student Support and Learning Resources in Universities	<i>E Woodberry and C Barnes</i>	427
Faculty Values and Expectations and Their Implications for Teaching, Learning and the Organization of Higher Education Institutions	<i>K Harman</i>	433
Flexible Learning in Higher Education	<i>S Alexander</i>	441
Innovation in Teaching and Curriculum Design	<i>J M Dearn</i>	448
Productivity of University Faculty Staff	<i>S Kyvik</i>	455
Promoting Effective Student Learning in Higher Education	<i>K Trigwell</i>	461
Student Attrition from Higher Education Institutions	<i>M Hayden</i>	467
University Students' Experiences of Higher Education	<i>C McInnis</i>	473
What Do University Students Learn?	<i>G D Kuh and B K Bridges</i>	479

Higher Education – Tertiary Education in a Globalized World

Associations of Universities	<i>G F Moodie</i>	485
Collective Bargaining in Higher Education	<i>C Allport, K McAlpine, and S Roberts</i>	491
Financing of Higher Education	<i>B Chapman and P Tulip</i>	499
Higher Education Crossing Borders	<i>J Knight</i>	507
Higher Education in Post-Conflict Societies	<i>M Daxner</i>	514
Higher Education in the New Economies	<i>J Fielden</i>	520
Human Resource Issues in Higher Education	<i>E El-Khawas</i>	527

L**Leadership and Management**

Leadership and Management Overview	<i>B Mulford</i>	695
------------------------------------	------------------	-----

Leadership and Management – as a Field of Study

Contexts for Leadership at the Beginning of the 21st Century	<i>M Bottery</i>	704
Educational Leadership: Philosophical Issues	<i>C W Evers</i>	710
Ethical/Moral Issues in Educational Leadership	<i>R J Starratt, L Langlois, and P Duignan</i>	717
History of Educational Leadership/Management	<i>R Bates</i>	724
Educational Leadership as a Field of Study: Professional Journals 1994–2006	<i>A R Thomas</i>	731
Research on Educational Leadership – Approaches/Promising Directions	<i>W A Firestone and V M J Robinson</i>	740

Leadership and Management – Leader Preparation

Leaders for Productive Schools	<i>J Murphy, S N Elliott, E B Goldring, and A C Porter</i>	746
New Approaches in Preparing School Leaders	<i>S G Huber</i>	752
Research for Leaders: The National College for School Leadership	<i>G Southworth</i>	762
School Leadership Standards	<i>L Ingvarson</i>	768

Leadership and Management – Leadership Issues

Effective Leadership in Challenging Schools	<i>A Harris</i>	777
Esthetics, Educational Leadership and Management	<i>R Bates</i>	783
Leader Mistreatment of Teachers	<i>J Blase and J Blase</i>	790
Leadership and Gender	<i>J Blackmore</i>	797
Leadership and Student Voice	<i>C Lanskey and J Rudduck</i>	803
Leadership and Urban Education	<i>K A Riley</i>	809
Leadership for Learning	<i>J MacBeath</i>	817
Leadership in Diverse Cultures	<i>A Walker and P K Yu-kwong</i>	824

Leading Diverse Schools	<i>J Ryan</i>	832
Supervision and Personnel Administration	<i>P D Tucker and D G Pounder</i>	839
The Big Challenge: Leadership for Inclusion	<i>M Ainscow and A Sandill</i>	846
The Educational Leader's New Work	<i>P Gronn</i>	852

VOLUME 5

Leadership and Management – Leadership Types

A Distributed Perspective on School Leadership and Management	<i>J P Spillane</i>	1
Leadership: Authentic	<i>P T Begley</i>	7
Leadership: Democratic	<i>J Møller</i>	12
Leadership: Instructional	<i>P Hallinger, K Leithwood, and R H Heck</i>	18
Leadership: Transformative	<i>C M Shields</i>	26
Strategic Leadership	<i>B Davies and B J Davies</i>	34
Teacher Leadership and Organizational Development	<i>A Harris</i>	40
Understanding How Leadership Influences Student Learning	<i>K Leithwood and B Levin</i>	45

Leadership and Management – Politics and Governance

Equity and Educational Effectiveness	<i>P Sammons</i>	51
Leading/Managing Schools in Communities Made Poor	<i>P Thomson</i>	58
Principals Role in Restructuring Schools	<i>G M Crow and K D Peterson</i>	66
School Reform and Restructuring: Self Managing School	<i>B J Caldwell</i>	72
System Leadership	<i>D Hopkins and R Higham</i>	78

Leadership and Management – School and Community

Educational Leadership and Social Capital	<i>J West-Burnham</i>	85
Networked Learning Communities School-to-School Collaboration as an Essential Component of a System Reform Strategy	<i>D Jackson</i>	92
Networks and Communities of Knowledge	<i>T Schuller and H Theisens</i>	100
School Community Relations	<i>R L Crowson and E B Goldring</i>	106
Social Capital, Educational Institutions and Leadership	<i>S Kilpatrick, S Johns, and B Mulford</i>	113

Leadership and Management – School Effectiveness and Improvement

Leadership and Technology	<i>C F Webber</i>	120
Leadership in the Implementation of Innovations	<i>I E Bogotch, T Townsend, and M Acker-Hocevar</i>	128
Leadership: School Improvement	<i>R H Heck and P Hallinger</i>	135
Organizational Learning in Schools	<i>B Mulford and H Silins</i>	143
Professional Learning Community	<i>L Stoll</i>	151
Transformational School Leadership	<i>K Leithwood</i>	158

Learning and Cognition – Issues and Concepts

Attention in Cognition and Early Learning	<i>M Heimann, T Tjus, and K Strid</i>	165
Concept Learning	<i>S J Unsworth and D L Medin</i>	172
Cooperative Learning	<i>R E Slavin</i>	177
Intelligence	<i>R J Sternberg</i>	184
Learning from Multiple Information Sources	<i>H I Strømsø and I Bråten</i>	191
Memory	<i>S Magnussen and T Brennen</i>	197
Metacognition	<i>L Baker</i>	204
Personal Epistemology in Education: Concepts, Issues, and Implications	<i>I Bråten</i>	211
Piaget: Recent Work	<i>L Smith</i>	218
The Adult Development of Cognition and Learning	<i>E A L Stine-Morrow and J M Parisi</i>	225
Vygotsky and Recent Developments	<i>J V Wertsch</i>	231

Learning and Cognition – Issues and Concepts – Focus on Cognition

Cognition and Emotion	<i>F Pons, M de Rosnay, and F Cuisinier</i>	237
Cognition: Overview and Recent Trends	<i>J Wiley and B D Jee</i>	245
Development of Creativity	<i>M A Runco</i>	251
Knowledge Domains and Domain Learning	<i>L Maggioni and P A Alexander</i>	255
Problem Solving and Human Expertise	<i>T J Nokes, C D Schunn, and M T H Chi</i>	265
Problem Solving and Reasoning	<i>R E Mayer</i>	273
Reasoning, Moral and Social	<i>N S Jampol, C B Richardson, and M Killen</i>	279
Remembering as Social Activity	<i>D Middleton</i>	285

Learning and Cognition – Issues, Concepts, Types

Computer-Supported Collaborative Learning: Basic Concepts, Multiple Perspectives, and Emerging Trends	<i>S R Ludvigsen and A I Mørch</i>	290
Learning as Inquiry	<i>S R Goldman, J Radinsky, S Tozer, and D Wink</i>	297
Learning Through Narrative Socialization	<i>A Fasulo</i>	303
Neuroscience Bases of Learning	<i>M H Immordino-Yang and K W Fischer</i>	310
The Neuroscience of Reading	<i>U Goswami</i>	317

Learning and Cognition – Issues, Concepts, Types – Focus on Learning

Learning Strategies	<i>C E Weinstein, J Jung, and T W Acee</i>	323
Learning Through Play	<i>K Aronsson</i>	330
Situated View of Learning	<i>A Collins and J G Greeno</i>	335
The Neuroscience of Aging and Cognition	<i>W J Hoyer and B Bessette-Symons</i>	340

Learning and Cognition – Language, Literacy and Subject-Related

An Overview of Language and Literacy in Educational Settings	<i>V G Aukrust</i>	345
Bilingualism and Learning	<i>L S Verplaetse and E Schmitt</i>	355
Classroom Discourse and Student Learning	<i>L Hemphill</i>	361
Early Writing	<i>B E Hagtvet</i>	367

First Language Acquisition	<i>N B Ratner</i>	375
Foreign Language Learning	<i>C Kinginger</i>	382
Learning Science	<i>J Leach and P Scott</i>	387
Learning to Read	<i>M S Burns and J K Kidd</i>	394
Mathematics Learning	<i>L Verschaffel, B Greer, and E De Corte</i>	401
Music Learning	<i>S Hallam</i>	407
Reading Comprehension: Reading for Learning	<i>C E Snow</i>	413
Second Language Learning	<i>J S Arnfast, J N Jørgensen, and A Holmen</i>	419
Writing: Advanced	<i>R Andrews</i>	426

Learning and Cognition – Other Issues

Gender and Learning	<i>L Yates and J McLeod</i>	432
Parent–Child Relationships in Early Learning	<i>C P Edwards, S M Sheridan, and L L Knoche</i>	438
Peer Interaction and Learning	<i>S Blum-Kulka and S Dvir-Gvirsman</i>	444

Learning and Cognition – Places of Learning

Learning in a Cross-Cultural Perspective	<i>L-F Zhang and R J Sternberg</i>	450
Learning Outside of School	<i>T Nunes</i>	457
Reasoning and Explanatory Talk: Learning in Everyday Settings	<i>D E Beals</i>	464

Learning and Cognition – Theoretical Perspectives – Learning

Apprenticeship Approach to Learning	<i>K Nielsen</i>	469
Connectionism and Learning	<i>T R Shultz</i>	476
Constructivism and Learning	<i>S Sjøberg</i>	485
Cultural–Historical Activity Theory	<i>A Havnes</i>	491
Learning in a Sociocultural Perspective	<i>R Säljö</i>	498
Self-Regulated Learning and Socio-Cognitive Theory	<i>P H Winne and A F Hadwin</i>	503

N

National Systems of Education

Australia	<i>C N Power</i>	510

USA	<i>B Pusser and M E R Lloyd</i>	888
Zanzibar	<i>I M Hija</i>	896

VOLUME 6**P****Philosophy of Education**

Philosophy of Education: Overview	<i>P Enslin</i>	1
-----------------------------------	-----------------	---

Philosophy of Education – Contemporary Issues

Neoliberalism, the Market and Performativity	<i>M A Peters</i>	11
Parents and Children's Rights	<i>M Clayton</i>	17
Peace Education	<i>I Gur-Ze'ev</i>	22
Philosophy and Educational Research	<i>D Bridges</i>	29
Race, Critical Race Theory and Whiteness	<i>B Applebaum</i>	36
School Choice and the Common School	<i>G Haydon</i>	44

Philosophy of Education – Philosophical Perspective

African Philosophy of Education	<i>K Horsthemke</i>	50
Feminism	<i>L Stone</i>	56
Hermeneutics	<i>C Bingham</i>	63
Islamic Education	<i>Y Waghid</i>	69
Liberalism and Education	<i>W Feinberg</i>	74
Phenomenology and Existentialism	<i>B Levering</i>	80
Pragmatism	<i>B Thayer-Bacon</i>	86
Psychoanalysis and Education	<i>P Smeyers</i>	92
Social and Cultural Capital in Education	<i>M Print</i>	97
The Aims of Education	<i>R Marples</i>	103
The Analytical Tradition	<i>D Carr</i>	108

Philosophy of Education – Philosophical Themes

Adult Learning: Philosophical Issues	<i>D Beckett</i>	114
Autonomy	<i>C A Wringe</i>	121
Bildung	<i>J Masschelein and N Ricken</i>	127
Critical Theory and Pedagogy	<i>M Mason</i>	133
Critical Thinking	<i>H Siegel</i>	141
Environmental Education	<i>M Bonnett</i>	146
Identity	<i>M S Merry</i>	152
Inclusion	<i>R Cigman</i>	158
Justice and Care	<i>M Tjiattas</i>	164
Lifelong Learning	<i>J Halliday</i>	170
Post-Structuralism and Education	<i>M Mason and M Clarke</i>	175
Reason and Rationality	<i>P Hogan</i>	183

Religious and Spiritual Education	<i>J C Conroy and S J McKinney</i>	189
The Capabilities Approach	<i>L Terzi</i>	194

Primary and Secondary Education – Learning and Teaching in School Age Education

Class Size – Arguments and Evidence	<i>P Blatchford and K C Lai</i>	200
Continuing Professional Development of Teachers	<i>P Earley</i>	207
Homeschooling	<i>P Farenga</i>	214
Innovations and Early Intervention in the Teaching of Literacy	<i>R E Slavin</i>	221
Personalized Learning in School Age Education	<i>D Hopkins</i>	227
Perspectives on Schooling in the Middle Years	<i>V J Russell</i>	233
Reform of the School Workforce	<i>H M Gunter and G Forrester</i>	242
Secondary Education in Developing Countries	<i>P Hughes and A Walker</i>	249

Primary and Secondary Education – Social Justice Issues in School Age Education

Community Focused Schools	<i>A Dyson</i>	255
---------------------------	----------------	-----

Primary and Secondary Education – The Effectiveness of School Systems

Reforming the American School System	<i>M Barber</i>	261
School Effectiveness in Developed Societies	<i>D Reynolds</i>	269
School to School Collaboration: Innovation and Improvement	<i>R Higham</i>	274
Studies of School Improvement in Developing Countries	<i>S E Anderson</i>	281
Sustainable Educational Reform	<i>A Hargreaves</i>	289
The Role of the District in Tri Level Reform	<i>M Fullan</i>	295
Whole School Designs for Enhancing Student Achievement	<i>S Stringfield and J Nunnery</i>	303

Q

Qualitative Research

Action Research in Education	<i>E Stringer</i>	311
Classroom Ethnography	<i>F Erickson</i>	320
Computer Assisted Qualitative Data Analysis	<i>C Silver and A Lewins</i>	326
Conversational Analysis	<i>H G Levine</i>	335
Critical Ethnography	<i>D Foley</i>	337
Critical Race Theory	<i>D Gillborn and G Ladson-Billings</i>	341
Critical Theory	<i>J J Ryoo and P McLaren</i>	348
Cultural Studies	<i>R Gaztambide-Fernández and K Cairns</i>	354
Cultural–Historical Activity Theory	<i>Laboratory for Comparative Human Cognition</i>	360
Design Experiments	<i>A Collins</i>	367
Discourse Analysis	<i>P Nikander and S Vehviläinen</i>	373
Document Analysis	<i>T Rapley and K N Jenkins</i>	380
Ethnography	<i>M Hammersley</i>	386

Ethnomethodology in Education Research	<i>D Macbeth</i>	392
Focus Groups	<i>D L Morgan and K Hoffman</i>	401
Grounded Theory	<i>K Charmaz and A Bryant</i>	406
Hermeneutics	<i>J Dyer</i>	413
Interpretive Research	<i>E Rauscher and M E Graue</i>	419
Interviews and Interviewing	<i>A Marvasti</i>	424
Life History	<i>J A Hatch and S K Newsom</i>	430
Narrative Inquiry	<i>D J Clandinin and J Huber</i>	436
Participant Observation	<i>J Schostak</i>	442
Phenomenology	<i>M van Manen and C A Adams</i>	449
Qualitative Case Studies	<i>S B Merriam</i>	456
Qualitative Data Management	<i>C Grbich</i>	463
Semiotics	<i>M Danesi</i>	475
Symbolic Interactionism, Naturalistic Inquiry, and Education	<i>J A Forte</i>	481
The Quality of Evidence in Qualitative Research	<i>S K Biklen</i>	488
Visual Data in Education Research	<i>J Wagner</i>	498

Qualitative Research – Standards of Proof

Validity: Mapping Diverse Perspectives	<i>G B Rossman, S F Rallis, and A M Kuntz</i>	505
--	---	-----

Quantitative and Qualitative Approaches to Research – Integration

Mixed Methods	<i>A Tashakkori and I Newman</i>	514
---------------	----------------------------------	-----

Quantitative Methods and Research Design

External Validity	<i>G E Matt, A Brewer, and M Sklar</i>	521
-------------------	--	-----

R

Role of NGOs in Globalization

NGOs and Globalization of Education	<i>M Ahmed</i>	529
-------------------------------------	----------------	-----

S

Social and Emotional Aspects of Learning

Achievement Goal Theory: Definitions, Correlates, and Unresolved Questions	<i>T Urdan</i>	537
Affect, Mood and Emotions	<i>S Schnall</i>	544
Anxiety	<i>M Zeidner</i>	549
Attribution Theory	<i>B Weiner</i>	558
Children's Friendship	<i>S R Asher and K L McDonald</i>	564
Coping with Stressful Situations: An Important Aspect of Self-Regulation	<i>M Boekaerts</i>	570
Culture in Motivation Research: A Challenging and Enriching Contribution	<i>K Kimmel and S Volet</i>	576
Early Social Development and Schooling	<i>G M van der Aalsvoort</i>	585

Emotion in Educational Contexts	<i>P A Schutz, P D Quijada, S de Vries, and M Lynde</i>	591
Empathy	<i>R Arnold</i>	597
Flow in Education	<i>J A Schmidt</i>	605
Interest	<i>M Ainley</i>	612
Intrinsic and Extrinsic Motivation	<i>C Levesque, K J Copeland, M D Pattie, and E L Deci</i>	618
Motivating Students in Classrooms	<i>J Brophy</i>	624
Motivation Regulation	<i>C A Wolters and S A Mueller</i>	631
Peer Learning in the Classroom	<i>N M Webb</i>	636
Poverty, Effects of on Social and Emotional Development	<i>N Philipsen Hetzner, A D Johnson, and J Brooks-Gunn</i>	643
Seeking Help as an Adaptive Response to Learning Difficulties: Person, Situation, and Developmental Influences	<i>S A Karabenick and R S Newman</i>	653
Self-Concept in Learning: Reciprocal effects model between academic self-concept and academic achievement	<i>H W Marsh and L F Scalas</i>	660
Self-Efficacy Beliefs	<i>D H Schunk and F Pajares</i>	668
Social and Emotional Outcomes of Learning	<i>J Vorhaus</i>	673
Social Aspects of Collaborative Learning	<i>M Arvaja and P Häkkinen</i>	685
Social Development and Schooling	<i>G W Ladd</i>	691
Social Interaction and Learning	<i>K Littleton</i>	698
Social Networks and the Education of Children and Youth	<i>B Schneider, T G Ford, and L Perez-Felkner</i>	705
Sociocultural Issues in Motivation	<i>R A Walker</i>	712
Socioemotional Aspects of Technology-Supported Learning	<i>S Järvelä</i>	718
Volitional Control of Learning	<i>J Husman and L Corno</i>	724
Wellbeing	<i>T Hascher</i>	732

VOLUME 7

Statistics

An Overview of Statistics in Education	<i>S Sinharay</i>	2
Analysis and Interpretation of Multivariate Data	<i>D J Bartholomew</i>	12
Analysis of Covariance	<i>N T Longford</i>	18
Analysis of Extreme Values in Education	<i>J Beirlant, G Dierckx, K Luwel, and P Onghena</i>	25
Analysis of Variance	<i>B M King</i>	32
Bayesian Statistical Analysis	<i>G Kokolakis</i>	37
Bootstrap Method	<i>K Singh and M Xie</i>	46
Canonical Correlation	<i>A Basu and A Mandal</i>	52
Categorical Data Analysis	<i>S E Fienberg and B W Junker</i>	58
Causal Inference	<i>D B Rubin</i>	66
Cluster Analysis: Overview	<i>S Landau and I Chis Ster</i>	72

Cognitive Psychology and Educational Statistics	<i>H S Kim and S Embretson</i>	84
Computational Statistics	<i>J E Gentle</i>	93
Continuous Probability Distributions	<i>S Sinharay</i>	98
Correspondence Analysis	<i>M Greenacre</i>	103
Data Mining	<i>R S J d Baker</i>	112
Decision Theory	<i>M Mendoza and E Gutiérrez-Peña</i>	119
Design of Experiments	<i>C A Albers and T R Kratochwill</i>	125
Discrete Probability Distributions	<i>S Sinharay</i>	132
Discrimination and Classification	<i>R C Neath and M S Johnson</i>	135
Empirical Bayes Methods	<i>E Ip and G Molenberghs</i>	142
Evaluation Research	<i>T Kellaghan</i>	150
Exploratory Data Analysis	<i>A Unwin</i>	156
Factor Analysis: An Overview and Some Contemporary Advances	<i>F A N Alhija</i>	162
Generalized Linear Mixed Models	<i>S Rabe-Hesketh and A Skrondal</i>	171
Generalized Linear Models	<i>J J Faraway</i>	178
Generating Random Numbers	<i>P J Pashley and A Amodeo</i>	184
Goodness-of-Fit Testing	<i>A Maydeu-Olivares and C García-Forero</i>	190
Graphical Models	<i>R G Almond</i>	197
Growth Modeling	<i>I Plewis</i>	203
Hierarchical Linear Models	<i>D Rindskopf</i>	210
Hypothesis Testing and Confidence Intervals	<i>T R Konold and X Fan</i>	216
Instrumental Variables	<i>E P Bettinger</i>	223
Jackknife Methods	<i>S Sinharay</i>	229
Large-sample Statistical Methods	<i>J M Singer and D F Andrade</i>	232
Latent Class Models	<i>J K Vermunt</i>	238
Markov Chain Monte Carlo	<i>A M Johansen</i>	245
Matrix Algebra	<i>H Yanai and H Ishii</i>	253
Measure of Association	<i>G-H Huang</i>	260
Measures of Central Tendency	<i>D Clark-Carter</i>	264
Measures of Dispersion, Skewness and Kurtosis	<i>D Rindskopf and M Shiyko</i>	267
Meta Analysis	<i>J Sánchez-Meca and F Marín-Martínez</i>	274
Missing Data	<i>C A W Glas</i>	283
Model Selection	<i>S J Haberman</i>	289
Monte Carlo Methods	<i>A M Johansen</i>	296
Multidimensional Scaling	<i>Z Zhang and Y Takane</i>	304
Multiple Comparisons	<i>C Lewis</i>	312
Multivariate Analysis of Variance	<i>N T Longford</i>	319
Multivariate Linear Regression	<i>S Ganesh</i>	324
Multivariate Normal Distribution	<i>J Tacq</i>	332

Nonlinear Regression Analysis	<i>H-H Huang, C K Hsiao, and S-Y Huang</i>	339
Nonparametric Statistical Methods	<i>K Sijtsma and W H M Emons</i>	347
Observational Studies	<i>P R Rosenbaum</i>	354
Order Statistics	<i>I Bairamov</i>	360
Point Estimation Methods with Applications to Item Response Theory Models	<i>F Bartolucci and L Scrucca</i>	366
Principal Components Analysis	<i>D J Bartholomew</i>	374
Probability Theory	<i>T Rudas</i>	378
Recursive Partitioning	<i>S Landau and S Barthel</i>	383
Sampling	<i>J Qian</i>	390
Sequential Probability Ratio Test	<i>T J H M Eggen</i>	396
Sequential Testing	<i>H J Vos</i>	401
Signal Detection Theory	<i>H Abdi</i>	407
Small Area Estimation	<i>A Noble</i>	411
Statistical Analysis of Functional Data	<i>F Ferraty, P Sarda, and P Vieu</i>	417
Statistical Inequalities	<i>H M Mahmoud and J L Gastwirth</i>	426
Statistical Paradoxes	<i>Y-K Tu</i>	429
Statistical Power Analysis	<i>L V Hedges and C Rhoads</i>	436
Statistical Significance Versus Effect Size	<i>X Fan and T R Konold</i>	444
Stochastic Processes	<i>F Baudoin</i>	451
Structural Equation Models	<i>S-Y Lee and X-Y Song</i>	453
Survival Data Analysis	<i>A F De Champlain</i>	459
The Normal Distribution and its Applications	<i>J Tacq</i>	467
Time Series Analysis	<i>P J Brockwell</i>	474
Univariate Linear Regression	<i>M L Hazelton</i>	482
Value-Added Models	<i>D F McCaffrey</i>	489

An Overview of Statistics in Education

S Sinharay, ETS, Princeton, NJ, USA

Introduction

This article intends to provide an overview of the application of statistics to the field of education. Statistics is a vast field, with new topics such as proteomics, ensemble sampling, and statistics in ophthalmology being introduced every now and then. The Statistics section of the encyclopedia did not attempt to provide a summary of all possible topics under the subject. Instead, this section focuses on the topics in statistics that have found applications in the field of education. Most applications of statistics to education are found in the area of educational measurement for the simple reason that statistics, the science that deals with quantitative analysis of data, inherently is related to measurement. (Several such applications – such as automated scoring, differential item functioning, generalizability theory, and item response theory (IRT) – are covered in the educational measurement section of the encyclopedia and will not be repeated here.) Hence, one could argue that some of

the topics included in the statistics section, or, that several examples included in the articles in this section, deal mostly with educational measurement and should have belonged in the Educational measurement section of this encyclopedia. In addition, some of the topics may overlap to a small extent with other topics in this section (e.g., generalized linear models are tools in categorical data analysis, but this section has two separate articles on the two topics). In any case, the number of applications of statistics to education is on the rise. This is because of (1) increases in computing power that have led people to ask questions that could not have been answered 20 years ago in a timely manner, and, (2) increases in the number of educational tests, partially due to the No Child Left Behind (NCLB) Act of 2001 in the USA that requires annual testing in the schools and produces a lot of data. Practitioners in education should find this section, together with the Educational measurement section, helpful as these two provide a comprehensive overview of the statistical methods used in education.

Next, several topics in statistics that are relevant to the field of education are described in brief along with, for some topics, examples of actual applications to the field of education. All of these topics and many more topics are covered in one or more articles in the statistics section.

Exploratory Data Analysis

After data are collected, often the first step in analyzing the data is exploratory data analysis (EDA), which consists of looking at data to see what they seem to say (Tukey, 1977) while relying on simple arithmetic and easy-to-draw pictures or plots. The techniques used in EDA include the following:

- Plotting the data in bar charts, pie charts, histograms, Youden plots, etc.,
- Plotting simple statistics in plots such as mean plots, standard deviation (SD) plots, box plots, etc., and
- Positioning such plots so as to extract the maximum information possible from them.

Consider **Figure 1**, which shows responses of 325 examinees to 15 items regarding mixed-number subtraction (Tatsuoka, 1984). An example item is $4\frac{5}{7} - 1\frac{4}{7}$. The items, sorted according to decreasing proportion correct (i.e., increasing difficulty), are shown along the x -axis in the figure; the examinees, sorted according to increasing raw scores, are shown along the y -axis. A short black horizontal line for an examinee and an item indicates a correct response. Some patterns are immediately visible from the figure. For example, several examinees (24 out of 325) at the top answer all items correctly (clear from the top of the plot being completely black). The examinees with the lowest scores could answer only two items correctly. Interestingly, these items ($\frac{3}{4} - \frac{3}{4}$ and $3\frac{7}{8} - 2$) are not the two easiest items and can be solved without any knowledge of mixed-number subtraction. Further, the lower half of the examinees rarely answered any difficult items correctly.

Wainer (2000, 2005) provided several applications of EDA to education.

Simple Summary Measures

It is often important to examine simple summary measures such as the mean and standard deviation (SD) of numerical information. For example, the *Digest of Education Statistics*, an annual publication of the National Center for Education Statistics (NCES) in the United States of America, includes the number of schools and colleges, teachers, enrolments, and graduates, in addition to other information on education. Further, the 2007 *Digest* reports that the average salary for teachers in 2005–06 was US\$49 109, about 1% higher than in 1995–96, after adjustment for inflation, and that the average reading scores at ages

Figure 1 A plot of the responses of 325 examinees to 15 mixed number subtraction items.

9 and 13 were higher in 2004 than in 1971 and the average score for 17-year-olds in 2004 was similar to that in 1971. Measures of central tendency and measures of dispersion, skewness, and kurtosis are discussed in the statistics section of the encyclopedia.

Measures of Association

In education, it is often of interest to examine the amount of association between a group of variables. For example, test administrators administering several tests simultaneously to students will like that scores on different tests (e.g., in reading, writing, mathematics, and science) do not correlate highly with each other. High correlations between such scores may raise questions about the need of so many tests. Choice of the appropriate measures of association depends on whether the variables of interest are continuous, discrete ordinal, or discrete nominal. For example, if the scores on the abovementioned tests are given on a scale of 1 to 100 in 1-point increments, a correlation coefficient may be the appropriate measure of association. On the other hand, if scores are given as 0 or 1 (where a score of 1 means that a student is good on a subject and 0 otherwise), an odds ratio or the Kendall's tau (see, e.g., Agresti, 2002) may be the appropriate measure. It is often of interest to examine the association between two groups of variables, $\mathbf{X} = (X_1, X_2, \dots, X_k)$ and $\mathbf{Y} = (Y_1, Y_2, \dots, Y_l)$. Canonical correlation analysis attempts to find linear combinations of the two groups with high correlations.

Probability Theory

Providing a mathematical description of our beliefs about the systematic properties of a random phenomenon is the first step in several statistical analyses. Usually this is accomplished with the help of probability theory, the branch of mathematics that describes the pattern of chance outcomes. A key idea in probability theory is that of a random variable, which is a variable whose value is a numerical outcome of a random phenomenon, and its distribution. There are several types of random variables, and the articles in the statistics section, on discrete and continuous probability distributions, provide detailed descriptions of them. A knowledge of random variables that follow a normal distribution is essential in several applications of statistics to education (e.g., the distribution plays a key role in topics such as factor analysis, analysis of variance, linear regression, and multilevel models) – hence two articles in the statistics section are devoted to these variables. Stochastic processes are sequences of random variables and are often of interest in probability theory (e.g., the path traced by a molecule as it travels in a liquid or a gas can be modeled using a stochastic process). Order statistics is another area of some importance in probability theory. For example, the ordered scores on a test of a sample of students represent the order statistics for the test score variable for the sample.

Statistical Inference

Statistical inference consists in the use of statistics to draw conclusions about some unknown aspect of a population based on a random sample from that population. Some preliminary conclusions may be drawn by the use of EDA or by the computation of summary statistics as well, but formal statistical inference uses calculations based on probability theory to substantiate those conclusions. Statistical inference can be divided into two areas: estimation and hypothesis testing. In estimation, the goal is to describe an unknown aspect of a population, for example, the average scholastic aptitude test (SAT) writing score of all examinees in the State of California in the USA. Estimation can be of two types, point estimation and interval estimation, depending on the goal of the application. The goal of hypothesis testing is to decide which of two complementary statements about a population is true. Two such complementary statements may be: (1) the students of California score higher on an average on SAT writing than the students of Texas, and (2) the students of California score lower on an average on SAT writing than the students of Texas. Point estimation is discussed in the statistics section of the encyclopedia. Details on interval estimation and hypothesis testing, and power analysis, which play a key role in hypothesis testing are also discussed in the statistics section of the encyclopedia. Often,

an investigator has to perform several hypothesis tests simultaneously. For example, one may want to compare the SAT critical reading scores of several pairs of schools belonging to a geographical region. The article on multiple comparison in the statistics section of the encyclopedia, discusses how to handle such a situation in an appropriate manner.

Principal-Components Analysis

Principal-component analysis (PCA) is often used to reduce multidimensional data sets to a lower number of dimensions for analysis. PCA retains those characteristics of the data set that contribute most to its variance, by keeping lower-order principal components (the ones that explain a large part of the variance present in the data) and ignoring higher-order ones (that do not explain much of the variance present in the data). Such low-order components often contain the most important aspects of the data. For example, in the National Assessment of Educational Progress (NAEP), a large-scale educational survey conducted in the USA (see, e.g., von Davier *et al.*, 2007), values of several hundred background variables are collected for each examinee. As it is important to use the information contained in these background variables in the statistical model used in NAEP, several principal components are computed from the original background variables and are used, instead of the original variable values, in the final NAEP statistical model (see, e.g., Jenkins *et al.*, 2001: 377–378).

Factor Analysis

The beginning of factor analysis lies in the early attempts of Karl Pearson, Charles Spearman, and others to define and measure intelligence – hence factor analysis has been a popular tool in education. When several tests are administered to a group of examinees, one aspect of validation may involve determining whether there are a few underlying abilities or skill variables that govern the examinees' performances on the tests. Factor analysis, which is often used in such situations, attempts to describe the covariance among several variables in terms of a few underlying, but unobservable, random variables called factors. For example, correlations from the group of test scores in classics, French, English, mathematics, and music collected by Spearman suggested an underlying intelligence factor (Johnson and Wichern, 1998). Factor analysis can be considered to be an extension of PCA – both of these techniques approximate the covariance matrix among the variables. A factor analysis is exploratory if the investigator does not have a hypothesis about the number of factors measured by the tests, and confirmatory if the investigator has such hypotheses and conducts statistical tests of them.

Structural-Equation Modeling

Structural-equation modeling is an extension of factor analysis and is a methodology designed primarily to test substantive theory from empirical data. For example, a theory may suggest that certain mental traits do not affect other traits and that certain variables do not load on certain factors, and that structural equation modeling can be used to test the theory. (A mental trait is a habitual pattern of behavior, thought and emotion.) A structural-equation model (SEM) is a system of linear equations among several unobservable variables (constructs) and observed variables. An SEM is composed of two parts: a structural part, linking the constructs to each other (usually, this part expresses the endogenous or dependant constructs as linear functions of the exogenous or independent constructs), and a measurement part, linking the constructs to observed measurements. The second part resembles a confirmatory factor analysis model. The SEMs can be displayed in visual form – these displays are called path diagrams. The full model is then estimated from a data set and inferences drawn.

Classification and Discriminant Analysis

The goal of classification and discriminant analysis are to describe, either graphically or algebraically, the different features of observations from several known groups, and to sort new objects (whose group membership is unknown) into the groups. For example, consider a medical school applications office that has the test scores and other college records of several students who became MDs and several others who did not. When a new application comes, the office may want to classify the applicant into likely to become MD and unlikely based on the test scores and college records.

Cluster Analysis

Cluster analysis is a technique to group similar observations into a number of clusters based on the observed values of several variables for each individual. Cluster analysis is similar in concept to discriminant analysis. The group membership of a sample of observations is known upfront in the latter while it is not known for any observation in the former. As an application of cluster analysis to education, Everitt (1990) describes a data set that has achievement test scores on reading and arithmetic for children in the fourth and sixth grades of 25 schools and the interest is in identifying different levels of performance and assessing similarities and differences in the patterns of change from fourth to sixth grade – cluster analysis is the most appropriate technique for the example.

Multidimensional Scaling

Multidimensional scaling is related to cluster analysis and assigns a location of each sample observation in a low-dimensional space so that their distances are close to their actual distances in multiple dimensions. This idea can be illustrated by reference to map construction. Suppose that one is given a table with the distances between several American cities (and not given the exact locations of them on a map). One could attempt to place the cities on a map so that the distances between the cities on the map are as close as possible to the distances on the table. Once this step is done, the map is used to draw conclusions on the sample; often, a cluster analysis is performed on these low-dimensional representations of the observations.

Categorical Data Analysis

A categorical variable has a measurement scale that consists of a set of categories. For example, the response of a student to a test question is often measured as correct or incorrect.

Categorical variables have two types of scales – nominal (when the categories do not have a natural ordering; e.g., gender and religion) and ordinal (when the categories have a natural ordering; e.g., patient condition being measured as good, fair, and serious). Several statistical methods and concepts have been devised for categorical data. For example, distributions such as the binomial and Poisson distributions, models such as generalized linear models, generalized linear mixed models, logistic regression model, and log-linear models, and methods such as analysis of contingency tables were devised to handle categorical data.

Analysis of Variance, Analysis of Covariance, and Multivariate Analysis of Variance

Analysis of variance (ANOVA) is the statistical procedure of comparing the means of a variable across several groups of individuals. For example, ANOVA may be used to compare the average SAT critical reading scores of several schools. The name of the technique arises from the fact that the first step in an ANOVA is to partition the variance present in the observations into several components. The ANOVA method was the second most frequently used data-analysis procedure in a survey of articles published between 1971 and 1998 in three reputed educational-research journals (Hsu, 2005). Generalizability theory (Cronbach *et al.*, 1963), which is a competitor to the classical theory of reliability of tests, usually applies ANOVA procedures to test scores.

Analysis of covariance (ANCOVA) is used when, like in ANOVA, the interest is in comparing several means, but the investigator also has the values of an additional variable that influences the variable of interest. For example,

ANCOVA may be used to compare the average SAT critical reading scores of several schools where the preliminary scholastic aptitude test/national merit scholarship qualifying test (PSAT/NMSQT) critical reading score of each examinee is available in addition to the SAT critical reading score. (The PSAT/NMSQT is supposed to provide firsthand practice for the SAT.)

Multivariate analysis of variance (MANOVA) is used to compare means of several variables simultaneously across several groups of individuals. For example, one could apply MANOVA to simultaneously compare the average scores on several subjects across several schools. Longford (1990) provides such an example.

Design of Experiments

An experiment is a test in which purposeful changes are made to the input variables of a process or system so that one may observe and identify the reasons for changes that may be observed in the output response. Design of experiments is the science of planning and conducting experiments and analyzing the resulting data so that valid and objective conclusions can be drawn. For example, the education ministry of a country may be interested in conducting an experiment to find out if a particular style of teaching mathematics helps children of fourth grade to learn the subject better than the existing style. In designing an experiment, the ministry has to make sure that any difference that they might observe in the outcome for students who were taught using the new style and those who were taught using the existing style cannot be attributed to a factor other than the teaching style (e.g., if they assign all students from rural areas to the new style and all students from urban areas to the existing style, then a difference can be attributed to the rural vs. urban difference). There are three basic principles in design of experiments – randomization (which means that the assignment of the experimental material and the order in which the individuals receive the experimental material are randomly determined), replication (which refers to repeats of each experimental condition), and blocking (which is the grouping of individuals to create several homogeneous groups before assigning the experimental material).

Observational Studies

In some situations, it is not possible (for reasons such as budget constraints and ethical issues) to design an experiment to answer a question or to test a hypothesis. For example, consider that the interest is in finding whether watching television is affecting the class grades of students. As watching television may have adverse effects, it will be unethical for one to design an experiment and randomly assign students to watch television for different number of hours per day. In such situations, often the only way is to conduct an observational study, that is, to

collect data on a sample of individuals, and apply an appropriate method to draw conclusions. In the example above, one could record the number of hours of television watched by the students and examine its association with their grades. Only limited number of conclusions can be drawn from an observational study. Any observed difference or association has several reasonable alternative explanations. For example, an observed lower score of students watching television longer can be caused by such students having less appropriate home and school inputs, such as fewer books at home or parents who read less to them. Huang and Lee (2009) investigated whether television watching at ages 6–7 and 8–9 affects cognitive development measured by math and reading scores at age 8–9 using a rich childhood longitudinal sample.

Causal Inference and Instrumental Variables

Suppose that an investigator is interested in testing a hypothesis, for example, about the comparison of a new educational program versus the existing program. Whether the investigator performs a randomized experiment or an observational study, he is faced with the question of how to draw inferences about the causal effects of the new program. In other words, if there is a performance difference between the students who were administered the new educational program and those who were administered the existing program, the investigator would like an answer to the question “Is the difference in performance of the two groups caused by the difference in the educational program?” An article in the statistics section discusses how causal inferences can be made. Instrumental variables (IVs) are used to estimate causal relationships when controlled experiments are not feasible. An overview of instrumental variables and of their possible applications to education is discussed in the statistics section of the encyclopedia.

Sampling

There is a growing importance of survey information on individuals, households, institutions, businesses, and environmental resources. Typically, one wants to gather information on a large group of individuals. However, time and cost usually does not allow obtaining information from each individual in the group. In such cases, one usually gathers information on only a sample, which is a small part of the large group. Sampling plays an essential role in drawing conclusions about the large group (which is called the population) from the information contained in the sample. An example of an application of sampling is the National Assessment of Educational Progress (NAEP), an educational sampling survey (Allen *et al.*, 2001). NAEP is the only ongoing measure of what students in the USA know and can do in a variety of subject areas and it reports scores for different demographic groups based on

gender, ethnicity, school type, school location, etc. NAEP draws a sample of students that is representative of the whole student population, applies several statistical techniques, and draws conclusions (an example of a conclusion is that between 1992 and 2000, the percentage of fourth-graders at or above the proficient-achievement level in reading increased by a small, but statistically significant amount) on the whole population based on information contained in the sample.

Bayesian and Empirical Bayes Methods

In a traditional or frequentist statistical analysis, the parameter of a probability model is considered an unknown but nonrandom quantity and only the information contained in the observed data is relevant for any inference. On the contrary, a Bayesian analysis (see, for e.g., Gelman *et al.*, 2003) assumes that the parameter is a random variable with a certain probability distribution, referred to as the prior distribution. The prior distribution quantifies the experimenter's beliefs about the parameter before observing the data. The next step in a Bayesian approach is to update the prior distribution on the basis of the likelihood function of the observed data through Bayes' theorem (Bayes, 1763). The resulting distribution is referred to as the posterior distribution of the parameter and summarizes the information in both the prior distribution and in the data. The influence of the prior distribution on the posterior distribution becomes weaker as the size of the observed data sample increases. The variation of the Bayesian methods in which the parameters of the prior distribution are estimated from the observed data is called empirical Bayes methods. Sinharay (2006) provided a review of the applications of Bayesian methods to educational measurement. Novick and Jackson (1974) included several applications of Bayesian methods to educational measurement. Other examples of applications of Bayesian methods to education are Rubin (1983), who applied Bayesian methods to three problems in educational measurement, Zwick *et al.* (1999), who applied an empirical Bayes method to differential item functioning, and Sinharay (2005), who applied Bayesian model-checking methods to assess the goodness of fit of IRT models. Further details on Bayesian methods and empirical Bayes methods (see, for example, Carlin and Louis, 1996) are discussed in the statistics section of the encyclopedia. Decision theory, which is a Bayesian approach, is concerned with identifying the values, uncertainties, and other issues relevant in a given decision and the resulting optimal decision. An article in the statistics section provides more details on decision theory.

Resampling Methods

Resampling methods (see, e.g., Efron, 1982) draw samples from the observed data to draw certain conclusions about

the population of interest. Two of the most popular resampling methods are the jackknife and bootstrap. Both of these are examples of nonparametric statistical methods.

Jackknife is used in statistical inference to estimate the bias and standard error of a test statistic. The basic idea behind jackknife lies in systematically recomputing the statistic a large number of times, leaving out one observation or a group of observations at a time from the sample. Estimates of the bias and variance of the statistic can be calculated from this set of jackknife replications of the statistic. The jackknife finds several applications in complex sampling schemes, such as multistage sampling with varying sampling weights – an example of such application is NAEP, where the jackknife method is employed to compute standard errors of estimates.

Bootstrap is a statistical method for estimating the sampling distribution of an estimator by sampling with replacement from the original sample, most often with the purpose of deriving robust estimates of standard errors and confidence intervals of a population parameter like a mean, median, and correlation coefficient. It is often used as a robust alternative to procedures based on parametric assumptions, especially when those assumptions are in doubt, or where parametric inference is impossible or requires very complicated formulas for the calculation of standard errors. See, for example, Hanson *et al.* (1993), who applied the bootstrap method to compute the standard error of an equating method.

Nonparametric Inference

Nonparametric methods, or distribution-free methods, are statistical methods that do not rely on assumptions that the data are drawn from a given probability distribution. Nonparametric methods are often applied when less is known about the data (so that a probability distribution cannot be assumed). Due to the reliance on fewer assumptions, nonparametric methods are more robust (i.e., less vulnerable to violations of assumptions). They are also often applied because of their simplicity. Examples of nonparametric methods are Pearson's χ^2 test for assessing independence in a contingency table, jackknife and bootstrap methods for estimating the bias and variance of an estimator, the Wilcoxon Mann–Whitney rank-sum test, the permutation test, the Kolmogorov–Smirnov test for assessing whether two distributions are the same, and spline regression for estimating regression curves of a dependent variable on several independent variables.

Multiple Linear Regression Models

Multiple linear regression models have been extensively used in education (see, e.g., Hsu, 2005). Interestingly, the name regression, borrowed from the title of the first article on this subject (Galton, 1885), does not reflect

either the importance or breadth of application of this method. Multiple regression is the statistical procedure to predict the values of a response (dependent) variable from a collection of predictor (independent) variable values. For example, if scores on multiple predictors and one criterion are available, multiple regression may be used to develop a single equation to predict criterion performance from the set of predictors. Several applications of multiple regression models can be found in the prediction of first-year grade-point average in college from the SAT scores and high school grade-point average (see, e.g., Kobrin *et al.*, 2008). Multiple regression and multivariate multiple regression, the case when there are more than one dependent variables of interest and the interest is in predicting them simultaneously from a set of predictor variables, are discussed in the statistics section of the encyclopedia.

Hierarchical Linear Models and Growth Models

In an application of linear regression, the observations are assumed to be independent. When the assumption of independence is likely to be violated, for example, in an application in which one has data on several students who belong to a few schools (so that the responses of the students within each school are dependent), a popular option is to employ hierarchical linear models (HLMs). These models are also referred to as multilevel models and random-effects regression models. The students constitute the lower level while the schools constitute the higher level in the example. Note that HLMs can also be applied to repeated measures design or longitudinal studies, where individuals are followed and their responses recorded several times over a certain period of time; the repeated measures constitute the lower level and the individuals constitute the higher level; examples of such models are growth models, where, for example, the investigator measures the cognitive growth of students by giving them several tests over a certain period of time. Growth models are increasingly popular in the US due to the NCLB Act of 2001 that puts special emphasis on the cognitive growth of students. For example, in December 2007, the US Secretary of Education Margaret Spellings invited all eligible US states to submit a growth model proposal for the 2007–08 school year. Growth models and HLMs are discussed in the statistics section of the encyclopedia.

Value-Added Models

The NCLB Act of 2001 in the US requires states to ensure that there are quality teachers in every classroom, with quality defined in terms of traditional criteria such as academic training and fully meeting the state's licensure

requirements (Braun, 2005). Interestingly, in this respect, some states have taken the lead by seeking a quantitative evaluation of teachers based on an analysis of the test-score gains of their students. Such evaluations employ a class of models called value-added models (VAMs). These models require data that track individual students' academic growth over several years in different subjects in order to estimate the contributions that teachers make to that growth. Thus, VAMs can be viewed as a special case of growth models and, hence, of HLMs. Given their current state of development, VAMs can be used to identify a group of teachers who may reasonably be assumed to require targeted professional development. These are the teachers with the lowest estimates of relative effectiveness. Despite the enthusiasm these models have generated among many policymakers, several technical reviews of VAMs have revealed a number of serious concerns and it is important that such concerns be properly addressed before VAMs are used to make important decisions.

Generalized Linear Models and Generalized Linear Mixed Models

Linear regression models apply when the response variable can be assumed to be a continuous variable or to be normally distributed. However, in several applications in education, the response does not belong to either of those types. Suppose the interest is in finding out how the socioeconomic status and average parents' education for a class of students affects their performance on a test. If we have the scores on the test for each student, we can employ a linear regression model regressing the test scores on the socioeconomic status and average parent education. However, if we do not have the scores, but only know who passed the test and who did not (which is a binary response), we cannot employ linear regression. Generalized linear models (GLMs) can be used in situations like this. GLMs are extensions of the linear regression model to a wider class of response type such as binary or count data. A GLM requires the specification of two defining characteristics – the distribution of the response and the link function that describes how the mean of the response is linked to a linear combination of the predictors. Generalized linear mixed models (GLMM) are extensions of GLMs to the case when the individuals are clustered (e.g., students belonging to different schools). The statistics section of the encyclopedia includes two articles, one each on GLM and GLMM.

Nonlinear Regression Methods

One is often interested in studying how a set of independent variables affect a dependent variable, but the relationship between them cannot be assumed linear. So

the abovementioned models, all of which assume a linear relationship, cannot be applied. Nonlinear regression methods, which may be applicable in such situations to predict the dependent variable from the independent variables and recursive partitioning, or, classification and regression trees method, which is another method that may be applicable in such situations, are discussed in the statistics section of the encyclopedia.

IRT Models

These models, with numerous applications in education, are discussed in an article in the educational measurement section and are not covered here.

Latent Class Models

A latent class model (LCM) relates a set of observed discrete multivariate variables to a set of latent variables (latent variables are not directly observed but are rather inferred, mostly through a mathematical model, from other variables that are observed; e.g., quality of life or intelligence of a person is a latent variable). It is called an LCM because the latent variable is discrete and divides the population into several classes. A class is characterized by a pattern of conditional probabilities that indicate the chance that variables take certain values. For example, Dayton and Macready (2006) discuss an application in which the observed variables are the responses to ten questions on matrix algebra on a test, the latent variable refers to the knowledge of matrix algebra of students, and the latent classes refer to masters and nonmasters on matrix algebra. Given class membership, the conditional probabilities specify the chance certain answers are chosen. Within each latent class, the observed variables are statistically independent (this is often called local independence). This is an important aspect of LCMs. Usually, the observed variables are statistically dependant. By introducing the latent variable, independence is restored in the sense that variables are independent within classes. The association between the observed variables is thus explained by the latent classes.

Time-Series Analysis

A time series is a sequence of data points, measured typically at successive time points. Time series analysis comprises methods that attempt to understand such time series, often either to understand the underlying context of the data points, or to make forecasts (predictions). Forecasting using a time-series analysis consists of the use of a model to forecast future events based on known past events. An example in education is the prediction of

the number of students who will take a test (e.g., SAT) at an administration based on the numbers from the previous administrations of the test. A time-series model generally reflects the fact that observations close together in time will be more closely related than observations further apart. Three broad classes of time-series models of practical importance are the autoregressive (AR) models, the integrated (I) models, and the moving average (MA) models. There are models, such as the autoregressive moving average (ARMA) and autoregressive integrated moving average (ARIMA) that are combinations of the above three.

Model Fit and Model Selection

Model fit analysis refers to an examination of whether the statistical model employed in an application adequately explains the important features of the data set at hand. Model selection refers to the choice of the statistical model that describes the data best among several competing models. Model fit and model selection analysis for the linear models employed in education do not pose any problems and proceed in a similar manner as in any other statistics field, for example, by using residual analysis, Akaike information criterion (AIC) and Bayesian information criterion (BIC) (see, e.g., Draper and Smith, 1998). However, model fit and model selection analysis for the nonlinear models, especially for the IRT models, are not trivial, primarily because the computations are not straightforward with these models, the response variable is discrete so that normality of the response cannot be assumed, and the number of possible responses is huge so that there is sparseness in the data. Fortunately, with the advent of faster computers, there has been substantial work in these areas. Swaminathan *et al.* (2006) provided a detailed review of the literature on model fit of IRT models. Several model fit statistics have been suggested for testing different aspects of an IRT model: statistics for testing the unidimensionality assumption of the IRT model, item fit statistics, person fit statistics, and overall model fit statistics. In applications of IRT models, it is important to employ the appropriate model fit statistics depending on the intended use of the model, and to evaluate not only statistical significance, but also practical significance. For example, it may happen that the value of a fit statistic is statistically significant so that the model does not predict an aspect of the data, but the misfit has negligible consequences operationally.

Kang and Cohen (2007) provided a detailed review of model selection methods for IRT models. More techniques such as the penalty criteria and the theoretical background behind several techniques are discussed in the statistics section of the encyclopedia.

Other Topics in Statistics

Large-sample methods are essential in the application of several statistical methods as it is often important to know the distribution of a test statistic for a large sample. An overview of how to handle multivariate data, which is common in the field of education, is discussed in the statistics section of the encyclopedia. There are several statistics topics that are of increasing interest to the field of education and will most likely become more popular in the coming years. Examples of such topics are analysis of extreme values, association mining, the relationship between cognitive psychology and educational statistics, correspondence analysis, data mining, functional data analysis, graphical models, instrumental variables, latent class analysis, missing data analysis, Monte Carlo methods, Markov chain Monte Carlo methods, sequential probability ratio test, small-area estimation, survival analysis, and signal detection theory. Hence, articles on these topics are included in this section. Computational methods play a key role in statistics in optimizing the time required to run computationally intensive statistical analyses on data. A knowledge of matrix algebra is important in several topics in statistics (such as linear regression, GLM, and ANOVA). Meta analysis, a technique for combining information from several studies, statistical inequalities and statistical paradoxes, which are three topics that any user of statistical methods should be aware of, are discussed in the statistics section of the encyclopedia. Random number generation is often an important issue in applications of statistics to education, especially those involving Monte Carlo or Markov chain Monte Carlo methods. Evaluation research, which is a form of disciplined and systematic inquiry that is carried out to arrive at an assessment or appraisal of an object, program, practice, activity, or system, is discussed in the statistics section of the encyclopedia.

Conclusions

The list of topics in statistics that is provided above, along with the examples of applications of these topics to education, demonstrate how statistics can be useful in education. As more students are tested, access to data becomes easier, computers become faster, and statistical software packages become more accessible, statistics is sure to find more applications in education. However, this situation also suggests the use of caution on several grounds.

Unless the investigator is careful, the resulting inference from a statistical analysis may be inappropriate. See, for example, Kramer and Gigerenzer (2005), of how statistics can be confusing and has been misused, Haller and Kraus (2002) to see how the concept of statistical significance is

misunderstood by university students and their instructors alike, and Stigler (2005) to see how correlation is often misinterpreted as causation. These works show that there is a need to apply appropriate statistical methods to educational applications. The articles in the statistics and educational measurement sections of this encyclopedia (along with the references and the further readings therein) will help practitioners in the field of education to learn more about statistics and to do a better job in choosing appropriate statistical methods in their applications.

There is often a tendency to fit complicated statistical models to real data. However, before using such a model, a researcher should always make sure that the model performs considerably better than a simpler alternative, both substantively and statistically, and that the model is well identified. It is important to remember the following comment in Rubin (1983)

William Cochran once told me that he was relatively unimpressed with statistical work that produced methods for solving non-existent problems or produced complicated methods which were at best only imperceptibly superior to simple methods already available. Cochran went on to say that he wanted to see statistical methods developed to help solve existing problems which were without currently acceptable solutions.

Glossary

Binary response – A variable which can take only one of two values, such as a yes/no answer to a question.

Categorical variable – A variable for which the observed values fall into categories, such as country of birth or socioeconomic class.

Correlation coefficient – A measure of the strength of the relationship between two variables.

Conventionally, 0 denotes no correlation, +1 a perfect correlation, and –1 a perfect negative relation.

Correlation matrix – A square table giving the correlation coefficients between all pairs of variables.

Dendrogram – A graphical way of presenting the results of cluster analysis; also called a tree diagram – hence the dendro- part of the name.

Latent variable – A variable whose value cannot be observed.

Manifest variable – A variable whose value can be observed.

Product moment correlation coefficient – A correlation coefficient measuring the closeness of a relationship to a straight line.

Introduction

Elementary statistical analysis is concerned with the case where we have just one observation per individual. In such cases our interest is usually in answering questions about how large the measurements are or how variable. The answers to such questions are provided by measures of location and dispersion. For further information, we often look at the frequency distribution to see the pattern of variation which lies behind these summary measures.

With multivariate data we may still be interested in looking at the variables individually, but there is now the possibility of investigating the relationships between variables. When we do this, we are doing multivariate analysis.

In education, for example, there may be measures of performance in a variety of school subjects. One might be

interested in how these were related to one another as, for example, if we wanted to know whether performance in mathematics was related to that in history. Or we might wish to bring demographic, or other, variables into the picture by asking whether overall performance depended on birth order in the family or on the time spent doing homework. When only two variables are involved, we speak of a bivariate analysis but this, of course, is only a special case of multivariate analysis where more than two variables are involved.

Multivariate data, therefore, arises whenever we make more than one observation on an individual. In education, such measures might be of performance in tests, demographic features, type of school attended, and so forth.

The Data Matrix

All multivariate data can be set out in what is called a data matrix and it is convenient to think about it in the following way. The conventional approach is to make the rows of the matrix correspond to persons, or whatever is the basic observational unit; the columns correspond to variables. It will be convenient to use x to denote any variable. In practice, such variables will have names, like score in French or school attended, but all such possibilities are represented by our x . A typical data matrix with n individuals and p variables will then appear as follows:

$$\begin{array}{ccccccc} x_{11} & x_{12} & \dots & \dots & x_{1p} \\ x_{21} & x_{22} & \dots & \dots & x_{2p} \\ \dots & & & & \\ \dots & & & & \\ x_{n1} & x_{n2} & \dots & \dots & x_{np} \end{array}$$

Two subscripts are needed to identify an entry in the table. The first tells us which row the individual is in and the second which column: x_{37} is thus the value for the third individual of the seventh variable. Such data might result from a survey in which a sample of n individuals gives answers to p questions or it might record the score of individuals on a set of tests. In practice, some of the values may be missing, because they were never obtained, have been lost, or have been withheld for some reason. This may materially affect what we can learn from the data.

We have spoken of the entries in the data matrix as values of some variable, like a test score but that is not always the case. Any piece of information can be entered

in a data matrix. It might, for example, be the place of residence or nationality. Again, this will determine what kind of analysis we can do but it does not affect the interpretation of the layout.

The Correlation Matrix

Multivariate analysis is about relationships and, in particular, relationships between variables, taken in pairs. The strength of these relationships is measured by correlation coefficients. The first step in any summarization of multivariate data is thus to obtain the pair-wise correlations between variables. In the case of metrical variables, we normally use the product moment correlations. These are measures of linear relationship and, if the relationship is not linear, it may be sensible therefore to first transform the variables in order to make the relationships approximately linear. If we denote the product moment correlation between variables i and j , by r_{ij} we may set the result out in the correlation matrix as follows:

$$\begin{matrix} 1, & r_{12}, & r_{13}, & \dots & r_{1n} \\ r_{21}, & 1, & r_{23}, & \dots & r_{2n} \\ \dots & \dots & \dots & \dots & \dots \\ r_{n1}, & r_{n2}, & \dots & \dots & 1 \end{matrix}$$

Since p will usually be much smaller than n , this matrix is much smaller than the data matrix and thus already represents a considerable reduction in the amount of information we have to take in. The diagonal elements are unity because each variable is perfectly correlated with itself. Almost all analyses of the data matrix start from the correlation matrix and it is always important to inspect this matrix before going further.

The correlation between two variables is, of course, the covariance between the standardized variables. By starting with the correlation coefficients, we ignore the scales of the original variables. This is often desirable because, in much of social science, the scales are themselves arbitrary. There are occasions, however, where the scales of measurement are relevant and should be taken account of in the analysis but we shall not pursue this possibility here.

What we have said relates to the case where all the variables are metrical. If some or all of them are not, the same kind of information can be conveyed by other types of correlation coefficient. Whether or not this will be a first step in the appropriate form of analysis will depend on what analysis is being carried out. With pairs of binary variables, for example, there are many possible coefficients of which the so-called tetrachoric coefficient is the closest to the product moment coefficient. There are other coefficients appropriate for pairs formed from

pairs of categorical (ordered or unordered) variables and for pairs where one variable is metrical and the other categorical.

Types of Data

Data come in many forms. The result of an examination may be recorded simply as pass or fail. For any individual this is often described as a binary response; collectively such responses are expressed as proportions or percentages. Sometimes an outcome may consist of one of a series of ordered categories as, for example, when the categories are: poor, fair, good, very good, and excellent. Otherwise, we may measure ability by a numerical score or a continuous scale as we would with something like weight. For simplicity, all of these levels of measurement may be grouped into two classes which we shall call categorical and metrical. The latter term is used to cover both discrete and continuous measured variables since we do not usually distinguish between them in multivariate analysis and it is convenient to have a single term to cover both. In many practical multivariate problems, we shall have a mixture of types as commonly happens with data derived from sample surveys. For example, some questions require categorical answers, such as place of residence and nationality. Others may be metrical as when we ask for income or age. The form which the analysis takes will depend very much on whether the variables are metrical or categorical but, conceptually, the logic underlying the methods will be similar.

Whether or not the data are obtained by experiment or observation, is another factor which affects the way they are interpreted. In an experimental situation, which is rather rare in the educational context, the conditions under which the variable values are obtained are controlled by the experimenter. One may, for example, test pupils under a variety of environmental conditions, where the individuals placed into each group can be chosen at random. More usually, we simply observe what is going on in which case we have no control over which factors, or combination of factors, are present. In such cases, it is much more difficult to infer causation.

An entirely different distinction has to be made between variables which are observed, called manifest, and those which are not, called latent. At first sight, this distinction may seem to be absurd because latent variables yield no data and hence would appear to be redundant. However, there are contexts in which there is reason to believe that there are other variables which may be relevant, but which cannot be observed. If these latent variables are in causal relationships with observable variables, we may wish to determine their influence and obtain other information about them indirectly through their effects, which we can observe.

Finally, we need to remind ourselves of the fact that individual values of a manifest variable may be unobserved not because they are latent, in the above sense, but because they have been lost or someone refused to answer a question or, for example, when a candidate in an examination did not have the time to complete all the questions in a test.

Summarization and Inference

The forms of multivariate analysis, which we shall review below, fall broadly into two categories. First, there are descriptive methods which aim to summarize multivariate data in a form where its message is more easily grasped. The calculation of a correlation matrix is an example of a descriptive method which is often a first step on the way to a more complete summarization. Second, there are inferential, or model-based, methods. In such cases, our analysis is of a sample from some population and the purpose is to learn something about the population from which the sample has been drawn, rather than about the sample itself. Thus, we might take a sample of schools and wish to infer something about the population of all schools. The step from the sample to the population can only be made, of course, if we know how the sample has been drawn. In practice, the method of sampling needs to be probabilistic. Probability theory then provides the link that we need to pass from sample to population.

An alternative, but equivalent, way of expressing much the same idea is by supposing that the data have been generated by a probability model. The purpose of the analysis is then expressed by saying that we wish to infer what the model is from what we observe in the values which it yields. For example, a set of test scores obtained by a group of pupils on a particular occasion may be thought of as just one sample among those that might have been obtained on other occasions.

There is a conceptual problem in moving from the univariate to the multivariate case. In univariate statistics, it is common to assume that the sample has come from a normal distribution. Even if this is not so, it is often possible to transform the variable to make it approximately normal. In the multivariate case, things are much more complicated because there are many multivariate distributions which have something in common with the normal distribution to choose from. The obvious candidate is the multivariate normal distribution which not only has the important property that the marginal distributions are normal, but also that the regressions are linear. For this reason, most of the theory of multivariate analysis is based on the assumption that the population distribution is multivariate normal. In the social sciences, in general, and the educational sciences, in particular, this assumption is highly suspect because many distributions of educational quantities are

far from normal (test scores are sometimes an exception). Although we shall mention several methods below, which were originally derived on the assumption of normality, they are less applicable and less generally used in the social sciences. Many of the textbooks of multivariate analysis are, however, based on the multivariate normal distribution and are thus less relevant to educational practice.

Dependence and Interdependence

The correlation matrix treats all variables on the same basis in which case any analysis may be described as interdependence analysis. Sometimes, however, the variables do not have the same status. In such cases, our interest may be in how some variables depend upon others; this arises particularly when there is a temporal ordering of the variables. We may then be interested in knowing how the later ones in the sequence depend on those which come earlier. For example, this might enable us to make predictions about the values of the later variables. The conceptually simplest, and best-known, example of dependence analysis is regression analysis where we have a set of variables whose values we wish to use to predict some other variable. For example, this might be from scores obtained in a job selection exercise where we may wish to predict the performance of a candidate on the job. Such predictions are essential in judging the aptitude of potential pilots, for example, when it is too costly or dangerous to test their ability in actual flight.

Methods

We shall now briefly review some of the multivariate methods which are available. These reviews give no technical material because they are designed to explain the main idea behind each method in such a way as to distinguish it from others. Almost all of the methods are described in more detail, and illustrated, in Bartholomew *et al.* (2008), and in other articles in this encyclopedia. We begin with descriptive methods of the interdependence variety.

Cluster Analysis

The object is to put sample members who are similar to one another into the same group, or cluster. Looked at in terms of the data matrix, we put together sample members (rows of the table) which are similar. This could be done crudely by eye but we need a method that is more objective and which can be programmed for a computer. To do this, we construct a measure of the similarity between any

pair of rows, or groups of rows. The simplest methods, called hierarchical, proceed by first grouping the closest pair of individuals, then, at each stage, grouping the closest pair of clusters already formed, and so on. In this way a tree, or dendrogram, may be constructed. The decision on when to terminate the clustering procedure is, essentially, subjective and usually depends on the meaningfulness of the clusters.

Multidimensional Scaling

This takes cluster analysis a stage further by locating sample members in space according to their distance apart. Similarity and distance are equivalent concepts, one being the inverse of the other: similar objects are close together and dissimilar objects are far apart. As the eye can only easily take in information displayed in two or, at most, three dimensions, the main interest lies in finding plots in two dimensions. The problem is then to locate sample members in a space of small dimension so that their distances apart are as near as possible to the distances calculated from the data matrix. The idea is often illustrated by reference to map construction. Atlases and books of reference often give tables showing the distances apart of towns or cities. If we had the distances only, we could attempt to reconstruct the map. This is a simpler problem in that we know in advance that the map is two dimensional. If we do not know the dimensionality, we have to try different numbers, in turn, to try to get a good fit.

The problem as we have described it is, more exactly, metrical scaling because the distances are treated as real distances. Nonmetric scaling is the term used when all we are entitled to assume is that the distances are ordered. This arises because, in social applications, we may feel confident in ranking the distances without wishing to go as far as assigning them precise values.

Principal Components Analysis

This method is applicable only when the elements of the data matrix are metrical variables. Its prime purpose is to reduce the dimensionality of the data. If there were only two columns in our data matrix, we could plot the rows as points in the plane. Inspection of the plot would then show the salient features of the data. For example, if the points fell close to a line, this fact would be clearly evident and we would recognize that the position of each point could be described by the single number defining its position on the line. If the data matrix has more than two columns, it will not be so easy to visualize the position, but we can still use the same geometrical ideas. Dimension reduction of this kind has been a requirement of educational testing for many years. Candidates may

obtain scores on a variety of subjects, or on repeated tests on the same subject, and we then wish to summarize them in, say, a single number. The traditional way of doing this has been to add them up, or average them, and use the result as a measure of performance. Principal components analysis (PCA) is a way of determining whether or not this is a reasonable process and whether one number can provide an adequate summary.

The correlation matrix is the starting point of PCA and it produces linear functions of the variables which have the property that they are uncorrelated with one another and that they are ordered according to the amount of the total variation for which they account.

Latent Variable Methods

Here we come to a family of methods which are often treated as quite distinct methods but which, in reality, are essentially the same. As in PCA, the key idea is to look for a much reduced number of variables in terms of which to describe the relationships in the data. Their novel feature is that their description is in terms of what we called latent (or unobserved) variables. One way of expressing their purpose is to say that they ask whether the correlation matrix can be explained by supposing that it arises from their dependence on a small set of unobserved variables. The oldest and best known of these methods is factor analysis. This applies when all of the variables involved, observed and unobserved, are metrical. Other methods include latent class analysis, latent profile analysis, and latent trait analysis. The relationship among these methods can be conveniently expressed in a fourfold table as set out below. This table is not exhaustive, as many hybrid models are possible, but it conveys the essential structure of the situation.

Classification of Latent Variable Models

In practice, categorical variables will often be binary, especially in educational applications where the observed variables may be right/wrong answers to test items (Table 1). There are extensive and self-contained treatments of these topics, especially latent trait analysis, but, in this introductory overview it is important to emphasize

Table 1 Observed variables and latent variables

<i>Latent variables</i>	<i>Observed variables (x)</i>	
	<i>Metrical</i>	<i>Categorical</i>
Metrical	Factor analysis	Latent trait analysis
Categorical	Latent profile analysis	Latent class analysis

the essential similarity rather than the differences. In practice, it is important to obtain a parsimonious summary of the data in terms of the latent variables. This often involves trying to identify them with substantive entities. For example, the early work on factor analysis, which was invented by Spearman in 1904, was concerned with his attempt to establish the existence of a common factor which he called general ability, or *g*. Latent trait analysis has similar objects when the observed variables are binary.

Regression Analysis

Regression analysis is the oldest, and probably, most widely used multivariate technique in the social sciences. Unlike the preceding methods, regression is an example of dependence analysis in which the variables are not treated symmetrically. In regression analysis, the object is to obtain a prediction of one variable, given the values of the others. To accommodate this change of viewpoint, a different terminology and notation are used. The variable being predicted is usually denoted by y and the predictor variables by x with subscripts added to distinguish one from another. In linear multiple regression, we look for a linear combination of the predictors (often called regressor variables). For example, in educational research, we might be interested in the extent to which school performance could be predicted by home circumstances, age, or performance on a previous occasion. In practice, regression models are estimated by least squares using appropriate software. Important practical matters concern the best selection of the best regressor variables, testing the significance of their coefficients, and setting confidence limits to the predictions.

Discriminant Analysis

Discriminant analysis is most simply thought of as regression analysis when the variable to be predicted is binary. Suppose that individuals belong to one of two categories to which we may assign the values 0 and 1. On each individual, we measure a number of quantities to help us determine to which category the individual belongs. How do we use these variables to help us decide the category to which the individual is to be allocated? One way to do this is to ask what linear combination of the variables best discriminates. This is essentially the same as asking for a way of predicting the category to which the individual belongs. To determine what is called the discriminant function, we need a sample for which the correct category is known. From this, we determine the regression equation treating the dependent variable as binary.

Path Analysis

Path analysis uses regression analysis to elucidate causal relations among a set of variables. For it to be applicable, the regressor variables must be ordered in time so that it is meaningful to speak of one variable being caused by those which precede it in time. A set of regression equations is then estimated so that each variable is regressed on those which precede it in time and on which it is presumed to depend.

Correspondence Analysis

Correspondence analysis originated in an attempt to elucidate the bivariate relationship between pairs of categorical variables. In that sense it may be regarded as a kind of correlation analysis. Multiple correspondence analysis extends the method to more than two categorical variables and in that form it may be regarded as having similar objects to PCA for metrical variables.

Multilevel Modeling

Multilevel modeling has found many applications in educational research; the models are also known under the names of hierarchical linear models, mixed models, and random effects models. It is used because it matches the structure so often found in educational systems where there is a hierarchy of levels. For example, at the lowest level, we have pupils who are grouped into classes which are part of schools and these, in turn, may be part of a region which, itself is embedded in a country. Sampling may take place at some or at all of these levels. Thus, suppose that there is a linear relationship between performance in an examination and parental income within a class, then that relationship may vary from class to class and school to school. The slope and intercept of any estimated regression equation may vary as we move between different levels of the hierarchy. Formally, we may allow the parameters of any regression model we fit to vary by treating them as random variables. It then makes more sense to estimate the parameters of the populations from which the sample is supposed to be drawn. From this brief description, it is easy to see how the various names for multilevel modeling are derived. There are several levels in the population being studied: the models are linear, the levels are arranged in a hierarchy, the models for each level are mixed together, and their coefficients are regarded as random.

Structural Equations Modeling

Factor analysis aims to explain the correlations among a set of observed variables in terms of a smaller set of latent

variables, or factors. Structural equation modeling takes this one step further by supposing that the latent variables themselves are interrelated. In particular, it is usually supposed that there are linear relations among the variables. It is therefore similar to path analysis except that the paths are between latent variables. This means that the regression equations have to be estimated indirectly from what we can observe – namely, the correlations (or covariances) among the observed variables. The starting point is thus the same as for factor analysis but more is asked of the method. In essence, we have to work out what we would expect the covariances to be if the model – which specifies the linear relations among the latent variables – were true. The parameters of the model are then estimated by choosing their values to make them as close as possible to the expected values. In practice, this is a difficult numerical problem which can only be solved efficiently by using appropriate computer software. The method is thus often known by the acronyms designating the many software packages which are now available, for example, LISREL, AMOS, EQS, Mplus, and GLAMM. As with any complex method of analysis, it is important to check the conclusions carefully as it is often the case that different models can lead to very similar covariance structures.

Glossary

Cause – A factor that can be manipulated; that is, its value could be set by design, in complete autonomy (not affecting any of the covariates).

Effect – Difference in the outcomes that can be attributed without any ambiguity solely to a specified cause.

Fixed effect – A factor that is constant across replications.

Hypothesis testing – A data-based procedure for deciding whether to contradict or not to contradict a specific conjecture (hypothesis).

Missing data – Data items that were meant to be collected (as per protocol), but were not.

Potential outcome – Outcome associated with the value of a factor (treatment), constant across the replications in which that value is assigned.

Random effect – A factor (a set of categories) that differs from one replication to the next.

Randomization – Assignment of the value of a factor made independently of the outcome, any covariates, or any attributes of the subjects.

Replication – A repeated application of a data-generating process that is independent of all the previous applications.

Variance – A measure of the dispersion of the values of a variable.

Introduction and Essentials

Analysis of covariance (ANCOVA) is used for studying the differences among a set of K groups. In each group, the outcome variable Y is related to one or several covariates (X) by ordinary regression. These regressions may have some features in common. As a simple example, suppose the outcome variable Y is a score on an educational test at time point 2, following a treatment, such as a course of study, and X is the score on a similar test, measuring the same trait, administered at time point 1, prior to the treatment. Suppose there are K treatments, each subject (student) is assigned to one of them, and this assignment is made completely at random.

In this example, the treatments $1, \dots, K$ form the groups, and the differences among the treatments are reflected

in the different regressions; the conditional expectation $E(Y | X = x; k)$ depends on k . We assume that the conditional distributions of Y given the value of X and the treatment k are independent; students do not influence one another's performances (e.g., by conferring during the exam, or by distracting one another). The simplest model of ANCOVA occurs when X is univariate and X and Y are jointly (bivariate) normally distributed, and

$$Y = \alpha_k + \beta X + \epsilon \quad [1]$$

where ϵ is a random sample from $N(0, \sigma^2)$, β (the regression slope on X) is a constant common to all the groups, and α_k are intercepts, specific to the groups $k = 1, \dots, K$. Thus, the regressions in [1] are parallel (see the left-hand panel of **Figure 1** for an illustration). The treatments have a straightforward ordering according to the values of α_k . Although the intercepts α_k depend on the origin and scale of X , the ordering of the treatments does not. Suppose we use $X^* = cX + d$ instead of X ; $c \neq 0$ and d are some constants. Then the model in [1] is equivalent to

$$Y = \alpha_k - \beta \frac{d}{c} + \frac{\beta}{c} X^* + \epsilon \quad [2]$$

and each intercept is altered by the same quantity $\beta d/c$.

The model in [1] reduces to analysis of variance (ANOVA) when β is set to zero or when there is no covariate X :

$$Y = \mu_k + \epsilon \quad [3]$$

ANCOVA is a regression model with one continuous and one categorical covariate, X and the group or treatment, respectively. It is expressed in the standard form by defining the indicators of the treatments:

$$I_i^{(k)} = 1$$

if subject i is assigned to treatment k , and $I_i^{(k)} = 0$ otherwise. To adhere to the standard form of the ordinary regression, we declare one of the treatments as the reference; no generality is lost by using treatment 1 for this purpose. Now

$$Y = \beta_0 + \sum_{k=2}^K \gamma_k I_i^{(k)} + \beta X + \epsilon \quad [4]$$

or, if the indices of the subjects and treatments are introduced,

$$Y_{ik} = \beta_0 + \gamma_k + \beta X_{ik} + \epsilon_{ik}$$

with the understanding that $\gamma_1 = 0$.

The coefficients γ_k are related to α_k in [1] by the identity

$$\gamma_k = \alpha_k - \alpha_1$$

The hypothesis that $\gamma_k = 0$ for a given treatment $k \neq 1$ is equivalent to $\alpha_k = \alpha_1$, and has therefore a meaning specific to the choice of the reference category. When the choice of this reference is arbitrary, such a hypothesis is not well motivated. The hypothesis that the constants α_k are all identical corresponds to $\gamma_2 = \dots = \gamma_K = 0$, that is, the K groups have a common regression

$$Y = \beta_0 + \beta X + \epsilon$$

This hypothesis is often well motivated and of practical interest.

The assumption of parallel regressions may be too restrictive. It is relaxed by introducing the interactions of the covariate X with the treatment:

$$\begin{aligned} Y &= \beta_0 + \sum_{b=2}^K \gamma_b I^{(b)} + \beta X + \sum_{b=2}^K \delta_b I^{(b)} X + \epsilon \\ &= \alpha_k + \beta_k X + \epsilon \end{aligned} \quad [5]$$

where k denotes the treatment that was applied, regarded as a variable (see the right-hand panel of **Figure 1** for an illustration). The treatments can now be compared by the values of the expectations $\alpha_k + \beta_k x$ for a range of (realistic) values x of X . Of course, the expectation $\alpha_k + \beta_k x$ for one treatment may exceed the expectation for another for some values of x and may fall short for other values. **Figure 2** gives several examples. In all panels except the bottom left-hand one, the treatments are well ordered, because the comparisons between the expected outcomes for pairs of treatments do not depend on x .

If a model, such as [5], is appropriate, then it is also appropriate when we replace X with $c + dX$ for some constants c and $d \neq 0$. We refer to this property as invariance with respect to linear transformations. It is a highly desirable property of any linear model when

instead of a particular version of the covariate X we could equally well have chosen one of its linear transformations.

The combination of invariance with respect to linear transformations of X and arbitrariness of the reference category yields the following rules for how the model in [5] can be simplified:

- The covariate X and all the indicators $I^{(k)}$ (the main effects) should be retained on the right-hand side (in the model) whenever the interactions $I^{(k)}X$ are included;
- all the $K - 1$ interactions $I^{(k)}X$ should be included in or excluded from the model *en masse*;
- when all the interactions $I^{(k)}X$ are excluded, the $K - 1$ indicator variables $I^{(k)}$, $k = 2, \dots, K$ should be retained in or excluded from the model *en masse*.

Corresponding to these rules are guidelines for which hypotheses are meaningful. Thus, it is meaningful to formulate and test only hypotheses that relate to the collection of the $K - 1$ interactions $I^{(k)}X$. Only when these are not present in the model is it meaningful to formulate and test hypotheses about the collection of the $K - 1$ indicators (treatment-contrasts) $I^{(k)}$ or about the (common) slope β . The hypothesis that a single or a subset of the interactions $I^{(k)}X$ have zero coefficients has a meaning contingent on the choice of the reference category.

Extensions to several covariates X are obvious. For each covariate we can define interactions with the treatment indicators $I^{(k)}$. In fact, interactions can be defined also among the covariates; then the invariance rules have to be extended. In principle, both main effects of an interaction have to be retained in the model, even though the values of the parameters associated with these main effects have no interpretation.

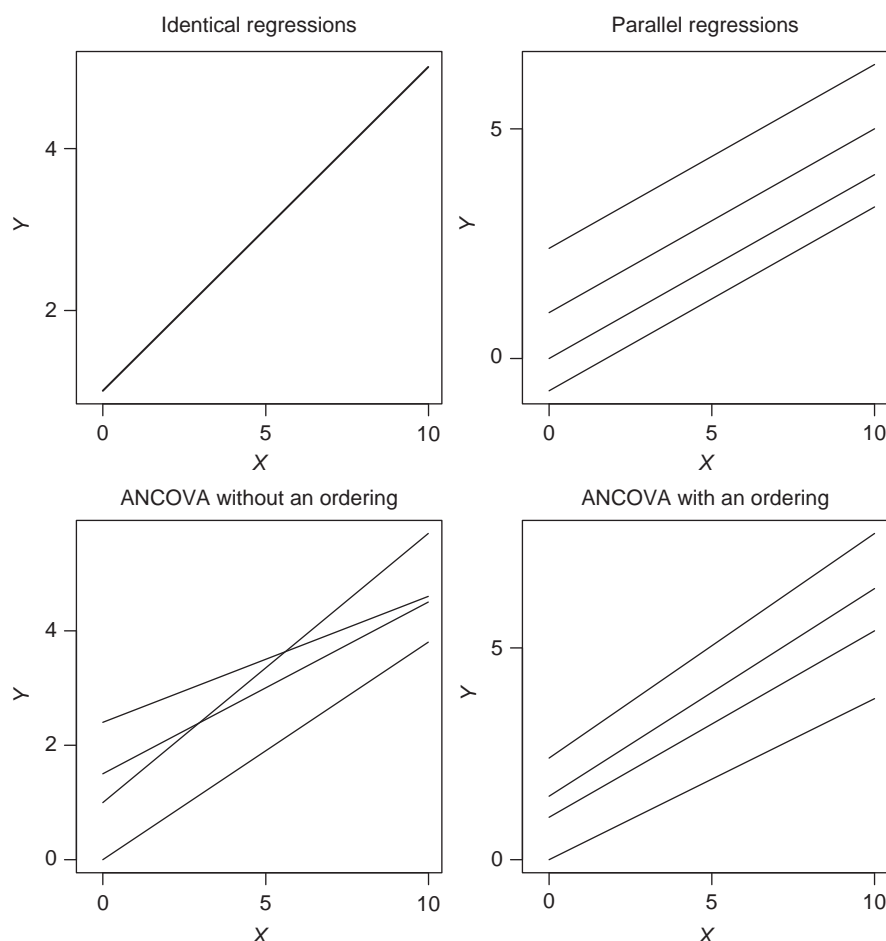

Figure 2 Patterns of the regressions in ANCOVA.

Further Details and Extensions

Random or Fixed

The groups are said to be fixed if they have the same identity in replications; that is, the subjects in the subsample for every group k are drawn from the same subpopulation. The subsample sizes n_k may vary (for a given k) across the replications, as may the values of X . The groups are said to be random, if there is a (large) population of groups, and the groups to be sampled from are themselves selected first, by a sampling process, before subjects are selected from each group to the sample. Thus, when groups are random, their identification (labeling) by the indices $k = 1, \dots, K$ is temporary because they are included in the study by chance. Summaries of the groups, such as the variance (matrix) of their coefficients β_k , may be relevant.

The Potential Outcomes Framework

Randomization of the subjects to treatments is a key design feature that enables a straightforward interpretation of

the model parameters in ANCOVA, as it is in ANOVA. It ensures that the treatment assigned does not depend on the vector of the so-called potential outcomes $(Y^{(1)}, \dots, Y^{(K)})$, which would be realized with the treatments $k = 1, \dots, K$. In practice, only one treatment is assigned to a subject, but in (hypothetical) replications a subject is not assigned the same treatment every time. In replications of the regression or ANCOVA, we have different sets of subjects but the same set of treatments $1, \dots, K$; the subjects are random and the treatments are fixed. If the subjects were also fixed, their outcomes would differ from replication to replication even if they were (or happened to be) assigned the same treatment, because a fresh (independent) ϵ is generated every time.

A framework alternative to ANCOVA assumes that each subject has a fixed vector of the potential outcomes $Y = (Y^{(1)}, \dots, Y^{(K)})$. In the population of subjects (students), these vectors may have a particular distribution, such as a K -variate normal, but for any one subject i who is included in two replications of the study and is assigned the same treatment k in both, the same outcome $Y_i^{(k)}$ is realized.

The problem of estimating any population summaries of Y , such as certain contrasts, can be formulated as a missing data problem. Suppose the entire population participates in the study. If the entire vector Y were observed for every subject, the inference would be straightforward. The observed values of the outcomes are regarded as the incomplete information and the values of Y for all the subjects as the complete information. The missing information is estimated, and the assignment process, which describes how treatments are assigned to subjects, is key. If the assignment is by randomization, the analysis is straightforward; if it depends on the values of the outcomes (e.g., when subjects select their treatment in pursuit of a specific agenda, such as the speediest and most complete recovery), complications arise. A general approach matches each subject which received a particular treatment with a similar subject which received a different treatment. Comparisons are then based on such matched pairs. An obvious advantage of this approach is that some of the assumptions specific to regression (normality, linearity, and homoscedasticity) can be dispensed with.

Multiway ANCOVA

For a small number of groups, no useful structures are usually defined. When there are many groups, they may themselves be clustered, so that cluster A contains a few groups, cluster B some others, and so on.

A group is formed by setting the category (level) of A, to k_A , and category of B, to k_B . For example, the two classifications may be two types of treatment, such as teaching style (say, four categories) and classroom size (two categories); then there are eight possible groups defined by crossing these two factors. Such settings are referred to as two-way designs and their analysis as two-way ANCOVA.

Factors may be nested within clusters. For example, the regions of a country may be the clusters, and its districts the groups. Districts are nested within regions if each district belongs to a single region, that is, when no district straddles regions. Groups are said to be crossed when two (or more) classifications are defined for them, such as classification A with K_A categories and classification B with K_B categories, and there is a category of either classification that does not determine the classification of the other. For example, the year of study and country of origin of students in a typical setting of a college are crossed classifications because some countries are represented in several years and in each year there are students from several countries.

Multiway ANOVA is defined by introducing further factors in the crossed design and further clustering in the nested design. Further, the features of clustering and nesting can be combined.

Other Generalizations of ANOVA

ANCOVA is a generalization of ANOVA in the following sense. In ANOVA, each group is associated with distribution, or model, $N(\mu_k, \sigma^2)$. In ANCOVA, groups are associated with conditional distributions

$$N(x\beta_k, \sigma^2)$$

where x is a vector of regressors (covariates) which include the intercept. Suppose the intercept is the first component of x , $x_1 = 1$. The regression parameter vector β_k has some of its components specific to each group k , and others common to all the groups k :

$$\beta_k = \begin{pmatrix} \beta_{k,\text{spe}} \\ \beta_{\text{com}} \end{pmatrix}$$

either part, $\beta_{k,\text{spe}}$ and β_{com} , may be empty.

More generally, the groups can be associated with any models, that is, conditional distributions, with sets of parameters θ_k governing them. These parameters may have some of their components specific and others common to the groups. The residual variance, if defined as one of the parameters in θ_k , should be common to the groups, and the conditional distributions should be normal, so that these models would be generalizations of ANOVA.

The models need not be related to ordinary regression. Generalized linear models have their ANCOVA versions, as do factor analysis and cluster analysis, stating that each group is associated with the same model (class of distributions), but the groups have different distributions, even if the values of some of their parameters are identical across the groups.

Hypothesis Testing in ANCOVA

In hypothesis testing in general, we specify a hypothesis as a submodel, often by specific values of some of the model parameters, and assess whether the data contain evidence against the hypothesis. For example, in a one-way ANCOVA with a single covariate X and parallel regressions (no interactions), we may specify as the (null-) hypothesis the submodel with identical regressions. We reject the null hypothesis if the data are not compatible with it. Hypothesis testing is conducted by defining a suitable statistic ξ and subset of its values, C , usually an interval or its complement. Then the hypothesis is rejected if the realized value of ξ is outside C .

A standard approach to deriving hypothesis tests is by the likelihood ratio method. Under some general conditions, such tests have good asymptotic (large-sample) properties. Likelihood ratio tests in ANCOVA have a particularly simple description in terms of the fitted (estimated) residual variances $\hat{\sigma}^2$. By way of an example we

give details of the test of the hypothesis that the regressions are identical, against the alternative that they are parallel:

$$H_0 : \gamma_2 = \dots = \gamma_K = 0$$

$$H_1 : \sum_{k=2}^{K-1} \gamma_k^2 > 0$$

Assuming H_0 , the estimator of the residual variance σ^2 has a scaled χ^2 distribution with $n - p$ degrees of freedom:

$$(n - p) \frac{\hat{\sigma}_0^2}{\sigma^2} \sim \chi_{n-p}^2$$

(n is the number of observations and p the number of covariates in the model, including the intercept). The estimator of the residual variance obtained when the alternative model is fitted has $K - 1$ fewer degrees of freedom, one for each additional parameter γ_k that is estimated:

$$(n - p - K + 1) \frac{\hat{\sigma}_1^2}{\sigma^2} \sim \chi_{n-p-K+1}^2$$

The subscript of $\hat{\sigma}^2$ indicates the model considered. Further,

$$(n - p) \frac{\hat{\sigma}_0^2}{\sigma^2} - (n - p - K + 1) \frac{\hat{\sigma}_1^2}{\sigma^2} \sim \chi_{K-1}^2$$

and this statistic is independent of $\hat{\sigma}_1^2$. The F statistic is defined as the ratio

$$F = \frac{(n - p - K + 1) \hat{\sigma}_1^2 - (n - p) \hat{\sigma}_0^2}{(K - 1) \hat{\sigma}_1^2}$$

under the hypothesis it has the F distribution with $K - 1$ and $n - p - K + 1$ degrees of freedom. The hypothesis is rejected for large values of F , so $C = [0, C^*)$ for suitably chosen value of C^* . As a convention, the size of the test, equal to the probability of (inappropriate) rejection when the hypothesis holds, is set to 0.05, and so the critical value C^* is set to the 95th percentile of the F distribution with $K - 1$ and $n - p - K + 1$ degrees of freedom.

The likelihood ratio test for a general hypothesis in ANCOVA proceeds as follows:

1. Specify the general model (B), and the hypothesis (A) as a special case of B, obtained by constraining the values of q parameters in B to given constants. Suppose B involves p model parameters.
2. Estimate the residual variance in both models, obtaining $\hat{\sigma}_A^2$ and $\hat{\sigma}_B^2$. Associate these estimators with their respective degrees of freedom, $n - q$ and $n - p$.
3. Evaluate the F -test statistic

$$F = \frac{\hat{\sigma}_B^2 - \hat{\sigma}_A^2}{\hat{\sigma}_A^2} \frac{p - q}{n - p}$$

4. Reject A if F exceeds the 95th percentile of the F distribution with $p - q$ and $n - p$ degrees of freedom.

This procedure is applicable only for null hypotheses specified by constraining one or several parameters to specific (default) values. Adaptations for some one-sided hypotheses, such as $\beta < 0$, are straightforward. When the hypothesis is that a parameter is in an interval, or a more complex set, several complications arise, the treatment of which, is beyond this article.

Example

In an educational study, a class of 95 students, split into four tutorial groups, were given an exam with an extended problem in probability theory, comprising 15 questions. One group was given the problem on its own, another group was also given hints on how to proceed, and the third group was provided the key definitions and explanation of the terms used. The fourth group was given both hints and the key definitions. Each student was graded on the scale 0–15, by adding up the separate scores for the questions, which themselves can be fractional (0–1, with 0.5, 0.25 and 0.75 quite common). As a covariate, each student's grade-point average from the previous year of study is available. It is recorded on the scale 5–10.

We want to assess the gain that can be attributed to the conditions of the exam, the provision of hints and the key definitions. Relevant to this is how the students are assigned to the tutorial groups. This is done in an administrative fashion, although students can switch from one class to another, so long as no class has too many students. This does not suggest any systematic *a priori* differences among the groups of students. However, the teaching assistants may differ in their qualities relevant to the instruction process, and so the four groups cannot be regarded as 'equivalent'. Furthermore, the treatment applied is confounded with the teaching assistant as a factor. That provides a rationale for adjustment by ANCOVA, and the student's grade in the previous year is regarded as a suitable proxy for it. Some core courses were taken by all students, but students had several optional courses. For simplicity and better illustration of ANCOVA, we disregard their differential difficulty, or strictness in their grading.

The data are plotted in **Figure 3** in four panels, with the observations for a group highlighted in each panel. The solid line is the regression fit to the data for the group, with the details given in the subtitle. The fit for the entire dataset, with the grouping ignored, is drawn by dashes; this fit is $\hat{y} = -3.35 + 1.67X$, with estimated residual variance $\hat{\sigma}^2 = 2.64$. The panels have identical scales, to make an informal comparison of the four groups easier.

The fit for the ANCOVA with no interactions is

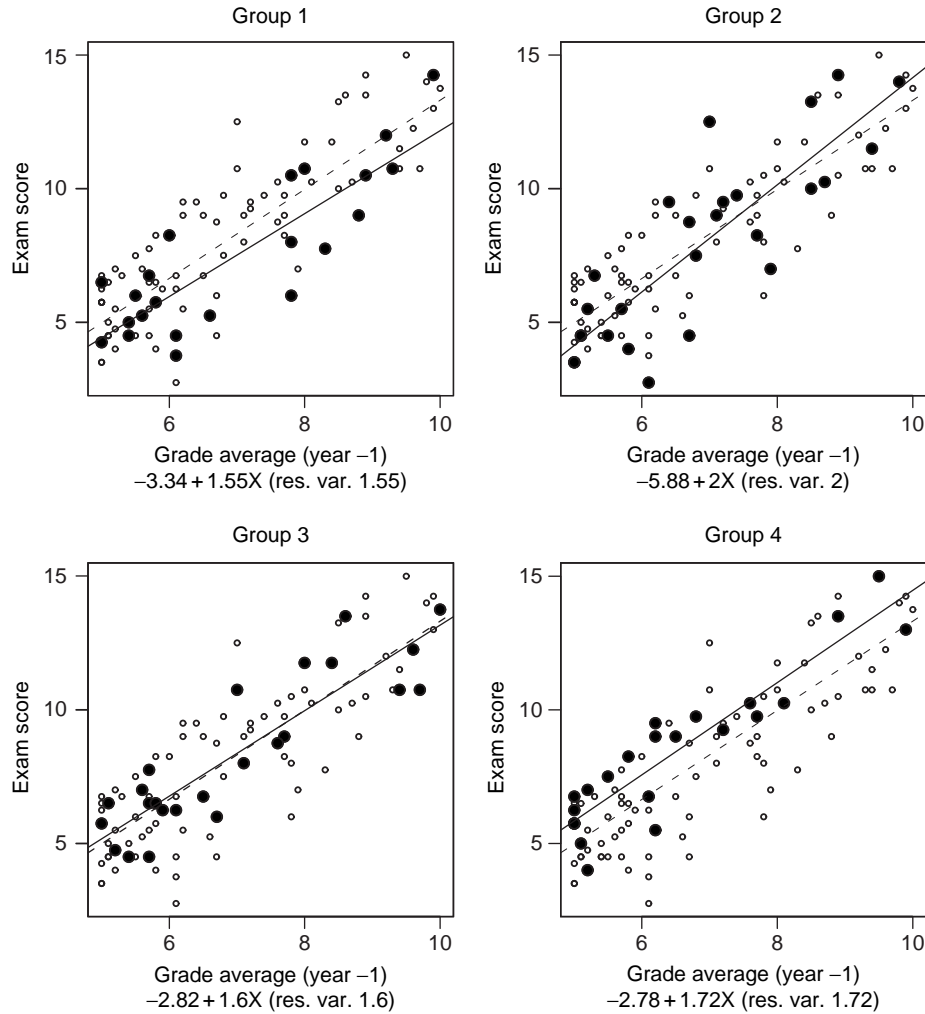

Figure 3 The exam scores and grade averages of the students in four experimental groups. Observations from the indicated group are highlighted (●) and the other observations are drawn by small open circles (o). The regression fitted to the observations in the group is marked by solid line, and the overall regression fit (ignoring the groups) by dashes.

Parameter	Intercept	Grade (Yr - 1)	Group (contrast)		
			2 - 1	3 - 1	4 - 1
Estimate	-4.50	1.72	0.59	0.86	1.78
Standard error		(0.10)	(0.44)	(0.45)	(0.46)

with estimated residual variance $\hat{\sigma}^2 = 2.32$. The display of the fit might invite the conclusion that there is no difference between groups 2 and 1 (judging by the comparison of the estimate 0.59 with the estimated standard error 0.44). Such a conclusion would be flawed, as would be the conclusion that the difference between groups 2 and 1 is small, unless we come to a consensus for what 'small' means. An informed student might reasonably argue that, for example, the difference of one point is far from small,

yet such a difference (between groups 2 and 1) is quite plausible.

To test the hypothesis that there are no differences among the groups (after adjusting for the grade in the previous year), we evaluate the F statistic:

$$F = \frac{2.64 \times (95 - 2) - 2.32 \times (95 - 5)}{2.32} \times \frac{1}{3} = 12.24$$

and compare it with the 95th percentile of the F distribution with 3 and 90 degrees of freedom, which is 2.70. As $12.24 > 2.70$, we conclude that we have evidence that the average performances of the four groups on the exam differ even after adjusting for grade average. With this conclusion, it is not appropriate to make it more specific and state that group 4 has the highest average (adjusted) performance, because the hypothesis tested was solely about differences, without their ordering.

Conclusion

ANCOVA is concerned with studying regressions in a set of groups. Models for ANCOVA cater for a wide range of patterns of these regressions and include procedures for selecting among them. As hypothesis testing is the principal method for this, its general limitations, especially in the context of several hypotheses, have to be carefully considered. Extensions of ANCOVA include structures for the groups, such as crossing, nesting, and their combinations, within-group models that are more complex than ordinary regression (factor analysis and generalized linear models), and the groups can be associated with random effects.

Goals of Extreme Value Theory

Extreme value methodology has been constructed with the specific aim to estimate extreme quantiles and/or small exceedance probabilities corresponding to rare events. Classical applications are the calculation of return periods of floods or other catastrophic events, or the prediction of large claims in insurance portfolios. In educational studies applications are less prominent but also here the statistical modeling of rare events can be of interest. We present an application to the modeling of reaction times in a numerosity test when applying the choice/no-choice method. This method involves testing participants under two types of conditions: (1) a choice condition in which participants can freely choose which strategy to use and (2) several no-choice conditions in which participants are required to apply a given strategy on all problems. Asking all participants to use a given strategy on all trials in the no-choice conditions excludes possible selection efforts and/or individual preferences, resulting in unbiased estimates of the speed and accuracy of the strategies under consideration. It also becomes possible to investigate participants' strategy adaptiveness by comparing their actual strategy choices under the choice condition with their ideal strategy choices based on the no-choice performance data.

The application is taken from Luwel *et al.* (2003) where the authors wanted to extend the applicability of the choice/no-choice method toward the domain of numerosity judgment. They aimed at developing a reliable and valid method for measuring the adaptiveness of numerosity judgment strategies, based on the procedure for strategy identification in the individual response-time patterns. Participants were instructed to determine, as quickly and accurately as possible, different numerosities of colored blocks that were presented in a 7 by 7 grid on a computer screen. This task allows for two main strategies: an addition strategy in which the different colored blocks in the grid are added and a subtraction strategy in which the number of empty squares is determined and then subtracted from the total number of squares in the grid. In contrast to the addition strategy which only involves one solution step, the subtraction strategy is a two-step strategy and therefore, cognitively more demanding. The experiment was performed under three conditions:

one choice (C) condition and two different no-choice (NC) conditions: (1) In the C-condition participants were free to use either the addition or the subtraction strategy, (2) in one NC-condition (i.e., the forced addition or FA-condition) all trials had to be solved by means of the addition strategy, and (3) in the other NC-condition (the forced subtraction or FS-condition) the use of the subtraction strategy was required on all trials. Thirty-seven students at the University of Leuven (Belgium) participated in this study. Their mean age was 21 years with ages ranging from 18 to 26 years. Each participant was tested individually and ran three different sessions. The presentation order of the different conditions was counterbalanced over participants with the important restriction that C-condition was always presented first. As a consequence all participants were randomly divided over one of both presentation orders: C/FA/FS or C/FS/FA.

In **Figure 1** the reaction times were plotted as a function of the number of blocks (from 1 to 49 blocks) for each of the three conditions: (1) FA-condition; (2) FS-condition and (3) C-condition. Some participants show extreme long reaction times. Whereas some statisticians would qualify these as outliers, the right skewness of the reaction times distribution (as a function of the block size) is always apparent and appears stronger for larger block sizes in the FA- and C-conditions, and for smaller block sizes in the FS-condition. Extreme value methodology provides models that allow one to model this right-skewness and the largest reaction times. More specifically, it tries to answer questions such as: what is, for a given number of blocks, the extreme reaction time level that occurs only once in 100 trials.

The Extreme Value Modeling Approach

The Basic Model

Here we present the extreme value theory (EVT) approach for pure random samples X_1, X_2, \dots, X_n . The population distribution is assumed to satisfy the domain of attraction condition which expresses that for large sample sizes n the statistical behavior of the maximum of such samples can be well approximated by a nondegenerate distribution which then is shown to be necessarily an extreme value distribution with cumulative distribution function

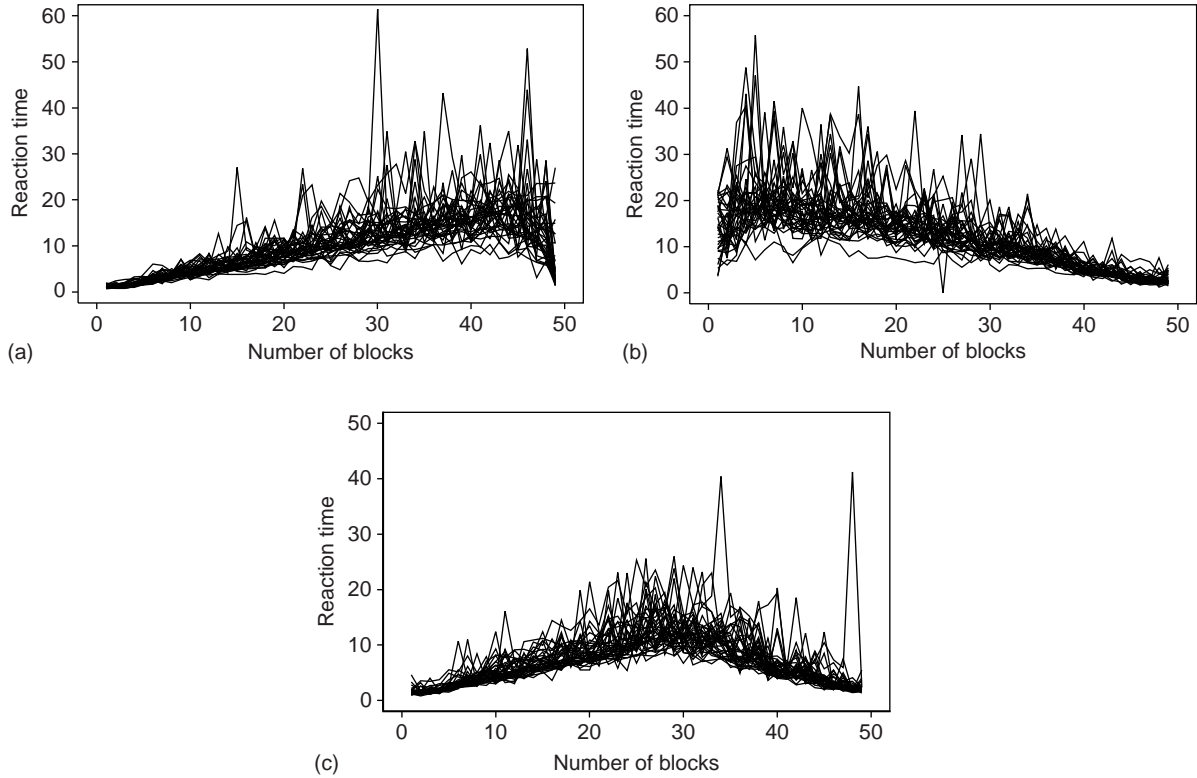

Figure 1 The reaction time (RT) as a function of the number of blocks for 37 participants: (a) addition; (b) subtraction, and (c) choice.

$$\exp[-(1 + \gamma y)^{-1/\gamma}] \quad [1]$$

The parameter γ , called the extreme value index (EVI), characterizes the tail decay of the underlying distribution F : a positive value of γ corresponds to heavy-tailed or Pareto-type distributions for which the density decays as a power law, while $\gamma = 0$ typically indicates an exponentially decreasing tail. Finally, $\gamma < 0$ indicates a distribution F with a finite right endpoint. This general condition is quite broad so that it does not really lead to restrictions in practice.

It can be shown that this framework is equivalent to assuming the following:

The POT-GPD assumption

For large enough threshold values t , the excesses, or peaks over threshold (POTs) $X - t$ (with $X > t$) approximately follow a generalized Pareto distribution (GPD) with cumulative distribution function $1 - (1 + \frac{\gamma}{\sigma} y)^{-1/\gamma}$.

In case $\gamma = 0$ the GPD is to be interpreted as the exponential distribution with cumulative distribution function $1 - e^{-y/\sigma}$ for $y > 0$. This discussion makes it clear that the goal of tail estimation is carried out under a nonstandard model which involves the choice of a threshold t . Of course, the estimation of the EVI parameter γ is an important step toward the goal of tail estimation.

Tail Estimation

The POT approach to estimate γ and $\sigma > 0$ simply consists of using for instance the maximum likelihood approach when fitting the GPD to the excesses $X - t$ for those data X which are larger than t . Quite often, the maximum likelihood estimation procedure leads to appropriate estimates $\hat{\gamma}_k$ and $\hat{\sigma}_k$ which show a stable behavior as a function of the threshold t . We refer to this method as the GP-POT approach.

Most commonly, t is chosen as one of data points itself, say as the $(k + 1)$ -largest observation, and then one lets k vary between 2 and the full sample size n . In **Figure 2** the POT estimators for the extreme value index of the RT values in our case study are shown for each of the three conditions as a function of $k = 2, \dots, 37$ with the number of blocks equal to 30. Remark that in case of the addition strategy the estimated values are clearly positive, while for the other two conditions values around zero are predominant. In **Figure 3** the POT estimators of γ obtained with $k = 17$ are shown for each condition as a function of the number of blocks. Comparing with **Figure 1** we remark that the appearance of high outliers in reaction times leads to predominant positive EVI estimates. **Figure 4** shows the corresponding maximum likelihood estimates of the scale parameter σ . While the POT estimates of the extreme value index do not seem to show trends with the number of blocks, the σ estimates grow linearly for the addition strategy, while

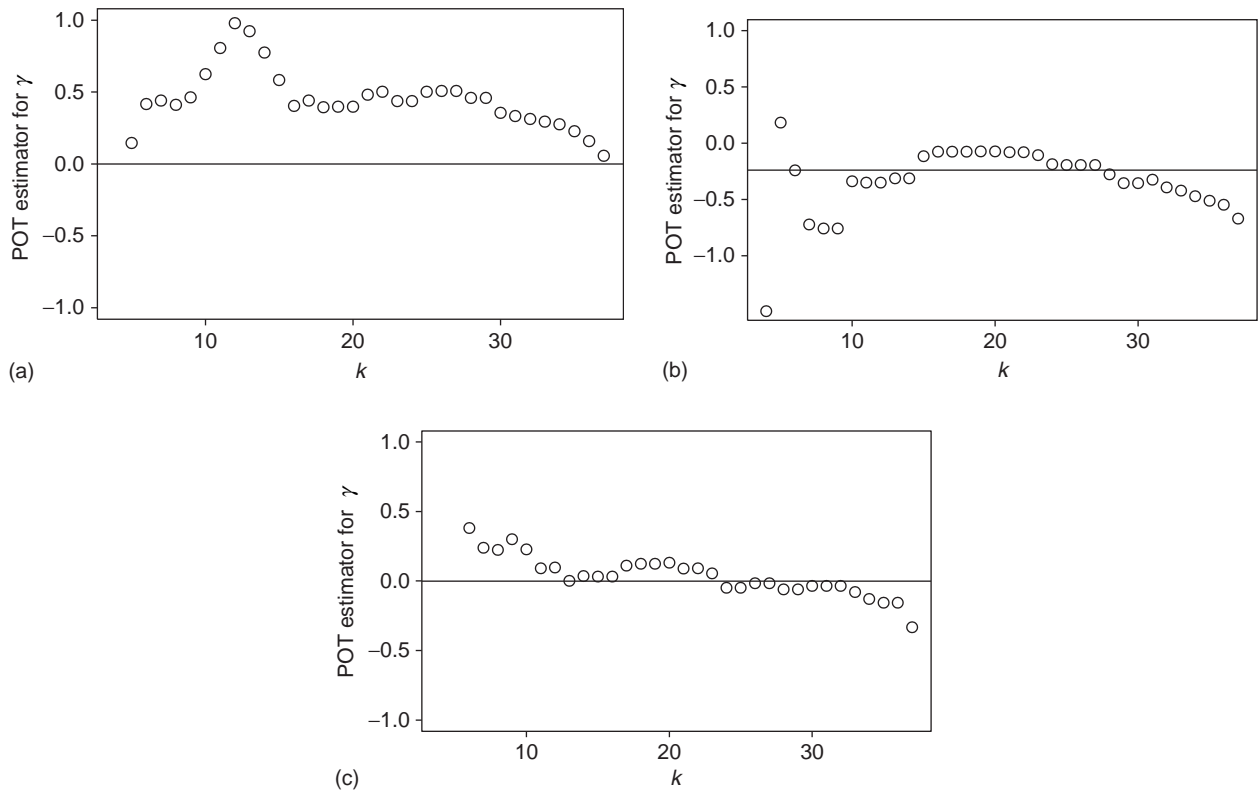

Figure 2 POT estimator for the extreme value index of the reaction times as a function of $k = 2.37$ (37 participants) for 30 blocks for: (a) addition, (b) subtraction, and (c) choice.

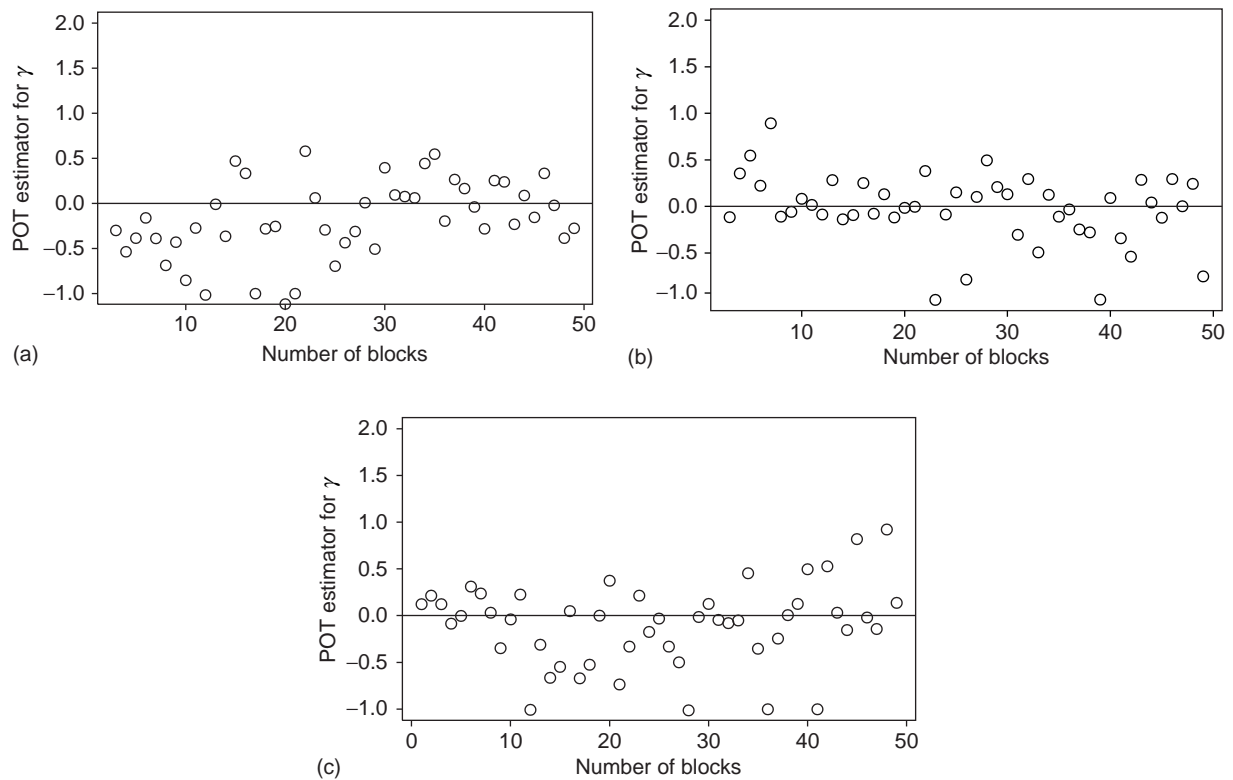

Figure 3 POT estimator of γ using the $k = 17$ largest RTs out of 37 observations for the extreme value index of the reaction times as a function of the number of blocks for: (a) addition, (b) subtraction, and (c) choice.

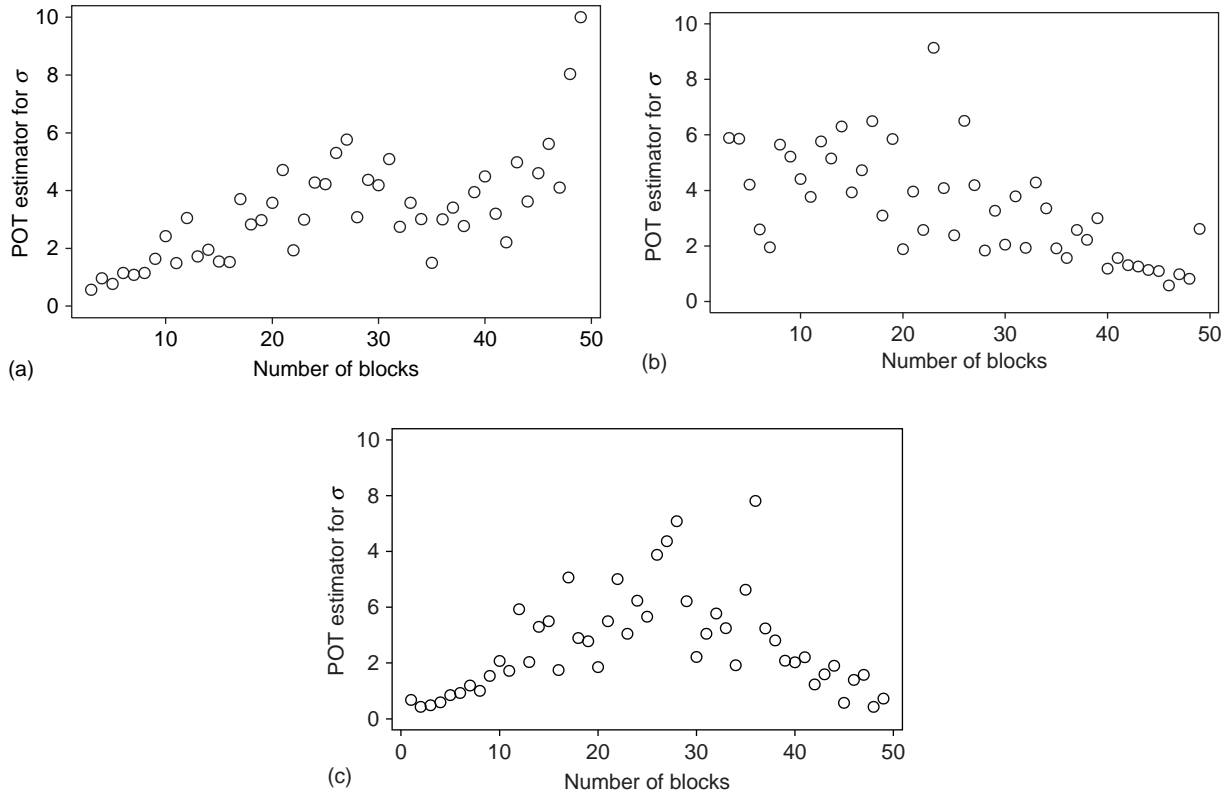

Figure 4 POT estimator of σ using the $k = 17$ largest RTs out of 37 observations for the extreme value index of the reaction times as a function of the number of blocks for: (a) addition, (b) subtraction, and (c) choice.

they decline linearly for the subtraction strategy. For the C-condition the scale estimates again follow the pattern of the original data plot as discussed in **Figure 1** with a change point at about 25 blocks.

Given estimators $\hat{\gamma}_k$ and $\hat{\sigma}_k$, how can one now estimate the exceedance probability p_x of obtaining an observation larger than a given large value x ? To this end the conditional probability of an excess being larger than x (where we restrict attention to the excess data and which is computed along the postulated GPD excess model) is to be multiplied with the probability that an observation is larger than the threshold. For the latter we assume that the threshold is situated deep enough in the sample so that the sample proportion can be used here as an estimate. This fraction equals k/n if the threshold t equals the $(k + 1)$ th largest observation. This leads to

$$\hat{p}_x = \frac{k}{n} \left(1 + \hat{\gamma} \frac{x - t}{\hat{\sigma}} \right)^{-1/\hat{\gamma}} \quad [2]$$

Moreover, an extreme quantile q_p which denotes the outcome level which is exceeded with a chosen probability p (typically smaller than $1/n$) can be estimated by equating [2] to p and solving for x :

$$\hat{q}_p = t + \hat{\sigma} \frac{(k/(np))^{\hat{\gamma}} - 1}{\hat{\gamma}} \quad [3]$$

Pareto-Type Distributions

In the special case $\gamma > 0$, the underlying distribution is member of the class of Pareto-type distributions. In this case the POT-GPD assumption is equivalent to the assumption that the excesses X/t (rather than $X - t$, $X > t$) for large enough t approximately follow a simple Pareto distribution (PD) with cumulative distribution function $1 - \gamma^{-1/\gamma}$, $\gamma > 1$. Again, using the $(k + 1)$ -largest observation as the threshold t , this leads to the following tail estimators that can be used in case $\gamma > 0$:

$$\hat{p}_x^+ = \frac{k}{n} \left(\frac{x}{t} \right)^{-1/\hat{\gamma}} \quad [4]$$

Remark that this is completely similar to [2] with the GPD replaced by the simple PD and the excess $x - t$ replaced by x/t . Also

$$\hat{q}_p^+ = t \left(\frac{k}{np} \right)^{\hat{\gamma}} \quad [5]$$

Here maximum likelihood estimation fitting the strict PD based on the excesses X/t ($X > t$) leads to the Hill (1975) estimator which equals the average of the logarithms of the excesses.

The use of the GPD in the general case $\gamma \in R$, respectively the PD in case $\gamma > 0$, as a consequence of theoretical probabilistic results concerning the distribution of maxima, should of course be validated in practice. One can validate the use of the fitted parametric models through goodness-of-fit methods. For this purpose for instance quantile plotting techniques can be used.

Quantile Plotting

An alternative view to the above material, which allows one to support an extreme value analysis graphically, consists of plotting the ordered data against the corresponding theoretical quantiles of the postulated model. For instance in the specific case of Pareto-type distributions ($\gamma > 0$), the model can be evaluated through the ultimate linearity of a Pareto quantile plot where the logarithm of the j th smallest observation is plotted against the standard exponential theoretical quantile $-\log\left(1 - \frac{j}{n+1}\right)$ ($1 \leq j \leq n$).

In **Figure 5** the Pareto quantile plots for the RTs to count 30 blocks at each of the three conditions are shown. These plots confirm the Pareto-type hypothesis for the corresponding reaction times as indeed above a certain level linearity becomes apparent. In **Figure 6** for

each condition the Hill estimators for $\gamma > 0$ at $k = 17$ are given as a function of the block size.

From **Figures 1–6** the problems arising with application of extreme value methods become apparent. First the choice of k is quite important. The higher the value k (or, the lower the threshold t) the higher the bias of the estimator since the models are only valid for threshold values approaching the endpoint of the underlying distribution. The smaller the k the larger the variance of the estimators because then these are based on fewer data. Also theoretically one can show that optimal k values are different for different estimators (such as the GP-POT and the Hill estimator). Also when only few data are available, such as is the case here with only 37 observations per number of blocks and per condition, the methods can be quite sensitive and yield different conclusions. In fact, the GP-POT approach here indicates a more nuanced picture concerning the signs and values of the EVI estimates, while the positive Hill estimates taken at $k = 17$ indicate EVI values around 0.2 for all numbers of blocks and all conditions. Also the GP-POT approach offers a more flexible framework offering two parameters in order to model the exceedances. In **Figure 7** we offer the GP quantile plots for the RTs corresponding to the counts of 30 blocks based on $k = 17$ exceedances for each of the three conditions. From

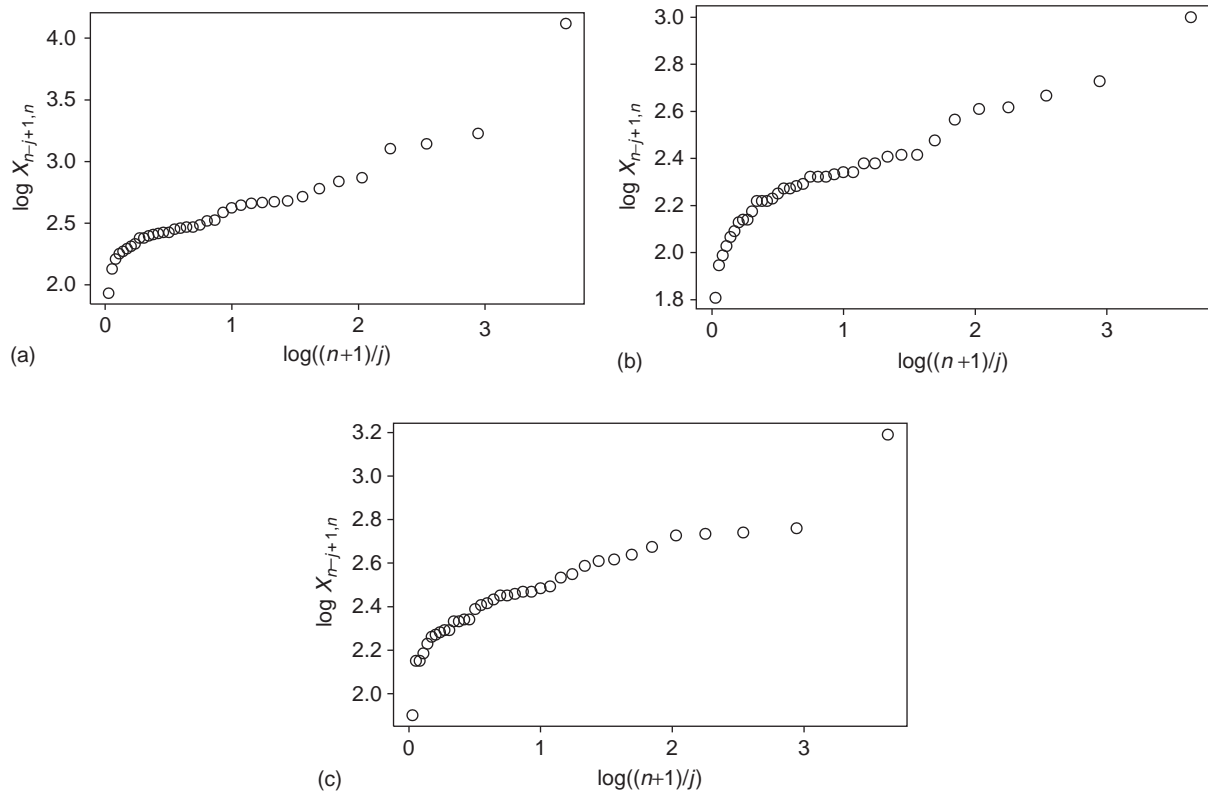

Figure 5 Pareto QQ plots for the reaction times to count 30 blocks. The data are based on results for 37 participants: (a) addition, (b) subtraction, and (c) choice.

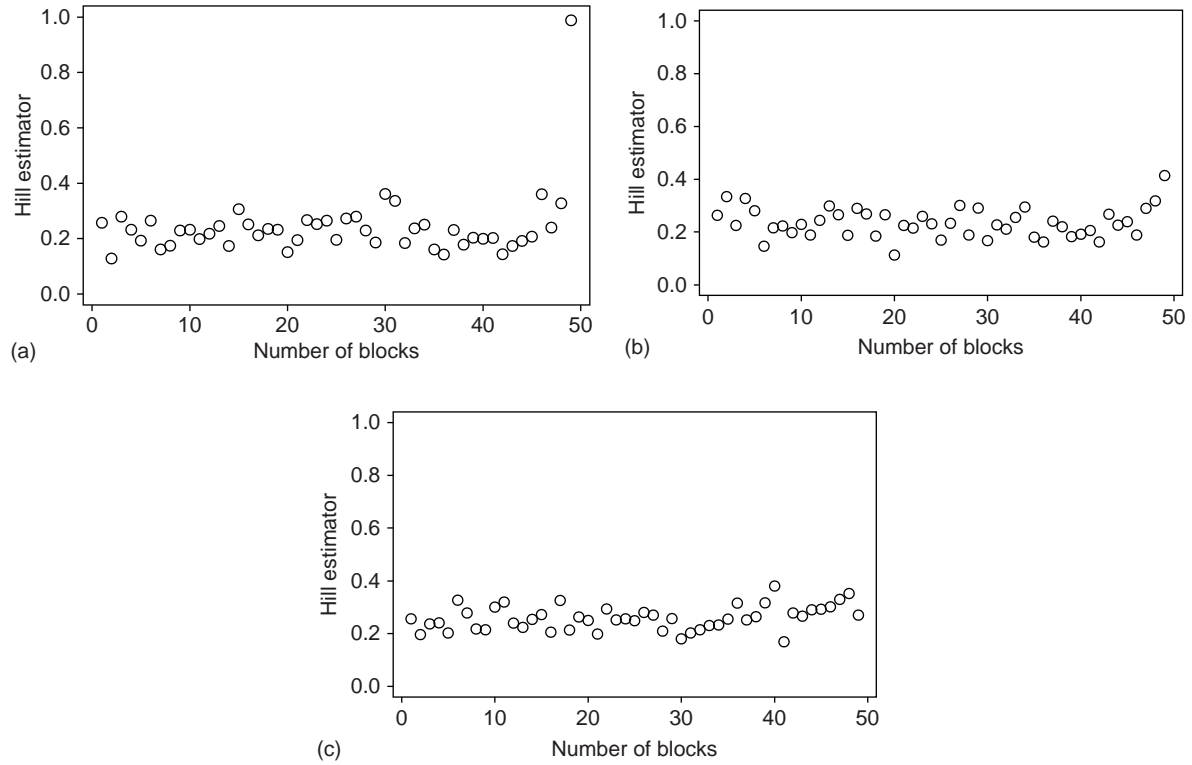

Figure 6 Hill estimator values when using the $k = 17$ largest RTs out of 37 observations for the extreme value index of the reaction times as a function of the number of blocks: (a) addition, (b) subtraction, and (c) choice.

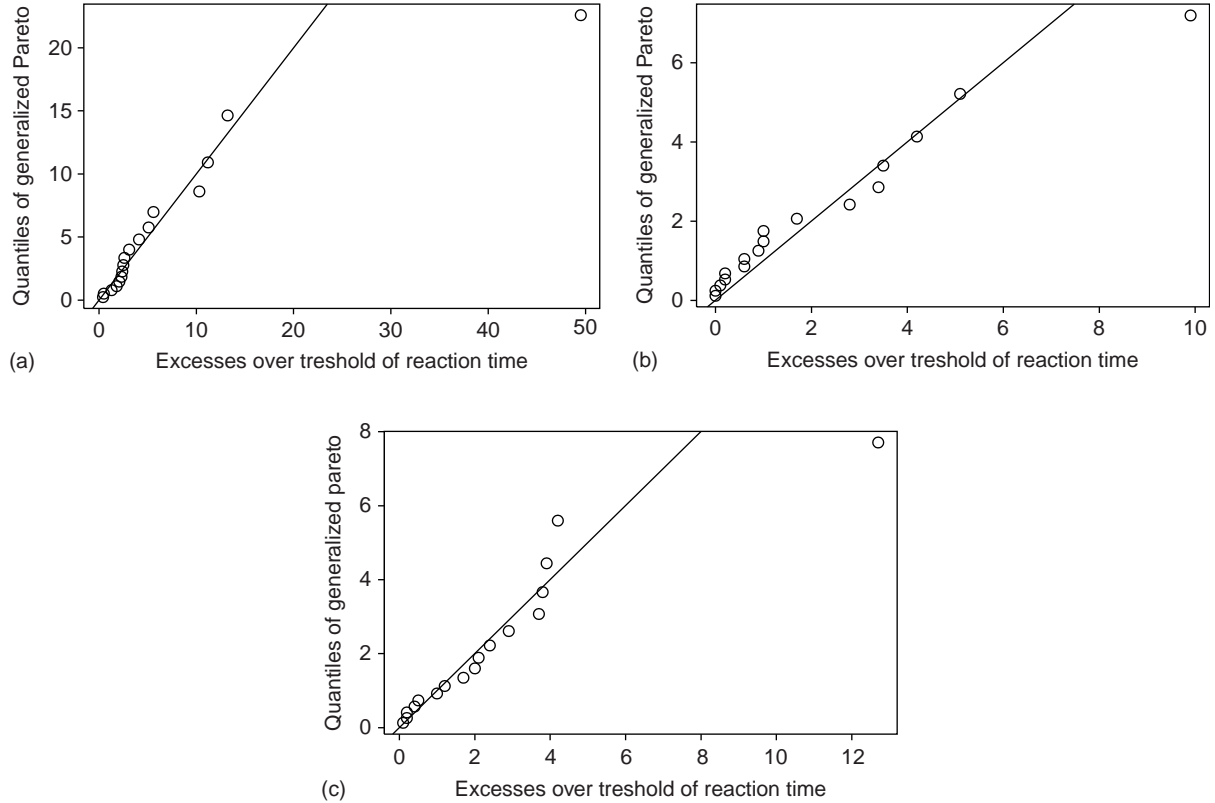

Figure 7 Generalized Pareto QQ plots for the excesses of the reaction times to count 30 blocks over the threshold corresponding to $k = 17$. The estimated γ and σ values for $k = 17$ are used: (a) addition ($\hat{\gamma} = 0.395, \hat{\sigma} = 4.186$), (b) subtraction ($\hat{\gamma} = 0.131, \hat{\sigma} = 2.048$), and (c) choice ($\hat{\gamma} = 0.125, \hat{\sigma} = 2.214$).

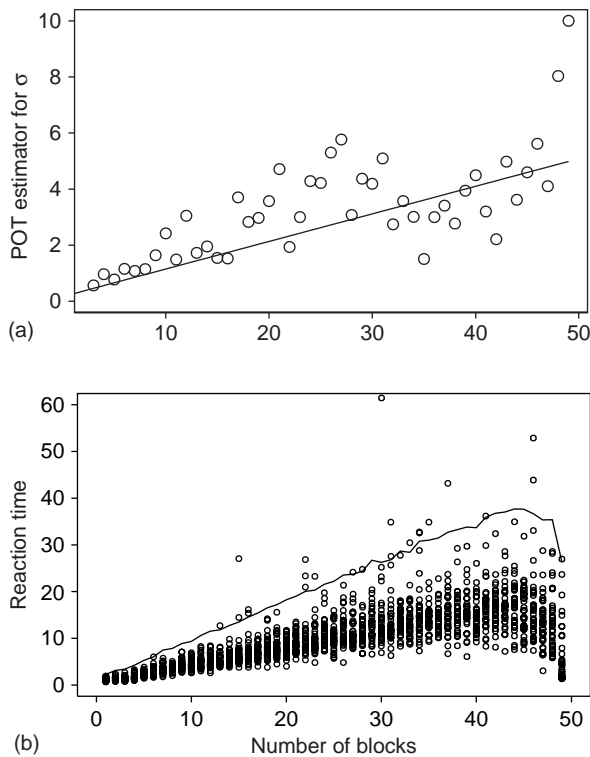

Figure 8 (a) The estimated linear σ -curve and (b) the 0.99 quantile curve based on regression modeling with the original data for the addition strategy data.

this we infer that the GP model appears accurate apart from the largest observation for each of the cases.

Extensions

Our case study motivates the use of regression models which allow one to retain the flexible modeling of the underlying distribution tails as proposed by the maximum domain of attraction framework. This then allows one to use more data points in order to estimate only a limited number of parameters, and hence keep a decent number of degrees of freedom. Davison and Smith (1990) provide an interesting regression modeling approach within the GP-POT modeling framework.

In the case of the addition strategy, we used maximum likelihood estimation to fit the GP distribution with parameters γ and $\sigma = \sigma_0 + \sigma_1 \times (\text{the number of blocks})$. For each number of blocks the 17 largest data points were used so that we used 49×17 excess data. This leads to the estimates $\hat{\gamma} = 0.096$, $\hat{\sigma}_0 = 0.167$, and $\hat{\sigma}_1 = 0.098$. Then

using the GPD as an excess model with σ substituted by the estimated regression function allows one to estimate a high quantile curve as a function of the number of blocks for the addition condition. In Figure 8 the estimated linear σ function is plotted with the original simple σ estimates as shown in Figure 4, next to the extreme quantile curve [3] corresponding with $p = 0.01$ with the original data under the addition strategy.

A Literature Review

In the last few decades extreme value methods in regression, multivariate, and time series settings have been developed and studied. More refined models designed to account for temporal dependence and multivariate data in extreme value analysis include Poisson process models, Markov chain models, and extreme value copulas. Another important issue is the choice of the threshold defining the excesses to which to fit the (generalized) PD. Recently developed techniques offer a solution through stabilizing the estimates over a large range of thresholds.

Analysis of Variance

B M King, Clemson University, Clemson, SC, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Alpha – The probability of a type I error (rejection of a true null hypothesis).

Analysis of variance (ANOVA) – A statistical test used to compare the means of three or more populations.

Factor – An independent (treatment) variable.

F ratio – $s^2_{\text{bet}}/s^2_{\text{wi}}$; between-groups variance estimate divided by the within-groups variance estimate.

Grand mean – The mean of all scores in all the treatment conditions.

Interaction effect – In analysis of variance, the joint effect of two or more independent variables that cannot be predicted from the main effects.

Level(s) – Different values of an independent variable (factor).

Main effect – In analysis of variance, the mean differences among the levels of one factor averaged across the levels of the other factor.

Omega-squared – $\hat{\omega}^2_{\text{bet}}$; a measure of effect size for analysis of variance.

Orthogonal comparisons – Comparisons that are unique and do not overlap.

Planned comparisons – Statistical tests used in place of ANOVA when the researcher knows in advance which comparisons are of interest.

Post hoc comparisons – Statistical tests performed after obtaining a significant value of F that indicates which means are significantly different.

Sum of squares (SS) – Sum of the squared deviations from the mean.

Type I error – Rejection of a true null hypothesis.

Imagine that you are superintendent of a school district and you wish to compare the mathematics competency of students enrolled in seven high schools. You randomly select 30 seniors from each school and give them a mathematics achievement test. Your null hypothesis is that the mean mathematics achievement scores in the seven populations (the seven high schools) are equal, that is, there is no difference in scores among the schools. How should you analyze the results? If you had decided to test for differences between all pairs of means with use of a t test, you would have to conduct 21 tests. Suppose that you had

decided in advance to set the probability of a type I error (rejection of a true null hypothesis) at 0.05. This means that when testing for a difference between two population means, in 20 replications of the same study (drawing independent random samples of the same size each time) you would expect the results of one of the t tests to be statistically significant even if there is no difference between the population means. Although for any one test, alpha (probability of a type I error) is 0.05, with 21 independent tests the probability of making at least one type I error is $p = 1 - (0.95)^{21} = 1 - 0.34 = 0.66$. Thus, if you found a statistically significant difference for one or two of your 21 tests, there is a high probability that the result(s) was due to a type I error rather than to a true difference between groups.

You need a test that allows you to make multiple comparisons among means while holding alpha steady at a preselected level. To this end, Ronald Fisher (1890–1962) developed analysis of variance (ANOVA) in the 1920s. An interesting feature of ANOVA is that although it is a test for differences among population means, it can be conducted without calculating the value of any of the sample means.

The Logic of ANOVA

When testing for differences among population means, variation in scores can be due to two things: chance and treatment effect. As the scores in any one sample are drawn randomly from the same population, the scores can differ from one another, and from the sample mean, only due to chance. Scores in different samples, as well as sample means, can differ from one another due to chance, but also because the experimental treatment has an effect. If there is no treatment effect, scores in different groups will differ only because of chance. Thus, when the null hypothesis (there is no treatment effect) is true, the variation of scores around the sample means within each sample ($X - \bar{X}$) and the variation of sample means from the grand mean ($\bar{X} - \bar{X}$; the grand mean, \bar{X} , is the mean of all scores) will both be a reflection of variation in scores due to chance factors.

For any study of two or more samples, the amount by which a score differs from the grand mean ($X - \bar{X}$) can be partitioned into two parts: the amount by which the score differs from its own sample mean ($X - \bar{X}$) and the amount by which the sample mean differs from the grand

mean $(\bar{X} - \bar{\bar{X}})$. The partition of $X - \bar{\bar{X}}$ is represented by the following equation:

$$X - \bar{\bar{X}} = (X - \bar{X}) + (\bar{X} - \bar{\bar{X}}) \quad [1]$$

As the name suggests, in ANOVA we are going to work with variance estimates. Variance estimates are calculated by dividing the sum of the squared deviations from the mean (often called sum of squares, and abbreviated SS) by the degrees of freedom (df). We can calculate the sum of squares total (SS_{total}) for two or more samples by calculating the deviation from the grand mean for every score, squaring each deviation score, and then summing (\sum) all the squared deviations from the grand mean:

$$SS_{\text{total}} = \sum_{\text{all scores}} (X - \bar{\bar{X}})^2$$

Look again at eqn [1]. You can see that we could also calculate SS_{total} by squaring $(X - \bar{X}) + (\bar{X} - \bar{\bar{X}})$:

$$\sum_{\text{all scores}} (X - \bar{\bar{X}})^2 = \sum_{\text{all scores}} (X - \bar{X})^2 + \sum_{\text{all scores}} n(\bar{X} - \bar{\bar{X}})^2 \quad [2]$$

where:

n = the number of scores in a particular group
 k = the number of samples

When we square $(a + b)$ there is a middle term, here $2(\bar{X} - \bar{\bar{X}})(X - \bar{X})$, but in this case it is always zero. What has been accomplished is the partitioning of the total sum of squares into two parts: (1) $\sum_{\text{all scores}} (X - \bar{X})^2$, called SS_{within} (or SS_{error}), a reflection only of chance factors when drawing samples, and (2) $\sum_{\text{all scores}} n(\bar{X} - \bar{\bar{X}})^2$, called SS_{between} , a reflection of both chance factors and treatment effect (when the population means are different). Thus,

$$SS_{\text{total}} = SS_{\text{within}} + SS_{\text{between}}$$

We can now divide the separate sums of squares by their respective degrees of freedom to obtain variance estimates. The degrees of freedom for SS_{total} is the total number of scores minus one: $n_{\text{total}} - 1$. For SS_{within} (abbreviated SS_{w}), the degrees of freedom is calculated by adding $n-1$ for each sample: $n_{\text{total}} - k$. For SS_{between} (abbreviated SS_{bet}), degrees of freedom is the number of samples minus one: $k - 1$.

The end result is two variance estimates. One is the within-groups variance estimate, $s_{\text{w}}^2 (= SS_{\text{w}}/df_{\text{w}})$, which is an estimate of the variance due to chance. It is sometimes called mean square within or mean square error. The other is the between-groups variance estimate, $s_{\text{bet}}^2 (= SS_{\text{bet}}/df_{\text{bet}})$, which is an estimate of the variance due to chance plus any treatment effect. When there is no treatment effect, both are estimates of the same thing. Thus, when the null hypothesis is true (i.e., there is no treatment effect), the ratio $s_{\text{bet}}^2/s_{\text{w}}^2$, called the F ratio,

should be about 1.0. When the null hypothesis is false, s_{bet}^2 will exceed s_{w}^2 , and the greater the treatment effect, the more is the amount by which s_{bet}^2 will exceed s_{w}^2 . Due to sampling variation, we expect the value of the F ratio to be different with every replication of a study (employing new randomly drawn samples of the same size). However, if we set $\alpha = 0.05$ and obtain a value of F that would have occurred by chance less than 5% of the time (if the null hypothesis were true) we reject the null hypothesis and conclude that there is a treatment effect (i.e., the treatment-effect reliably exceeds effects due to chance).

Computation of F : An Example

Let us look at an example. Suppose that we wish to compare two new methods for teaching mathematics with the standard method. We randomly draw a sample of ten subjects for each method and use each method for 1 year, at the end of which we administer a mathematics achievement test to each subject. The hypothetical results are as follows:

Standard method (X)	Method 2 (Y)	Method 3 (Z)
68	85	62
70	90	76
75	80	74
65	78	70
55	82	58
80	86	78
72	92	74
78	76	80
60	94	65
74	84	75
$\sum X = 697$	$\sum Y = 847$	$\sum Z = 712$
$\bar{X} = 69.7$	$\bar{Y} = 84.7$	$\bar{Z} = 71.2$
$\bar{\bar{X}} = 2256/30 = 75.2$		

We now calculate SS_{total} , SS_{w} , and SS_{bet} :

$$\begin{aligned}
 SS_{\text{total}} &= (68 - 75.2)^2 + (70 - 75.2)^2 + \cdots + (65 - 75.2)^2 \\
 &\quad + (75 - 75.2)^2 = 2722.8 \\
 SS_{\text{w}} &= (68 - 69.7)^2 + (85 - 84.7)^2 + (62 - 71.2)^2 \\
 &\quad + (70 - 69.7)^2 + (90 - 84.7)^2 + (76 - 71.2)^2 \\
 &\quad + \cdots + (74 - 69.7)^2 + (84 - 84.7)^2 + (75 - 71.2)^2 \\
 &= 1357.8 \\
 SS_{\text{bet}} &= 10(69.7 - 75.2)^2 \\
 &\quad + 10(84.7 - 75.2)^2 \\
 &\quad + 10(71.2 - 75.2)^2 \\
 &= 1365
 \end{aligned}$$

There are formulas to calculate SS_{total} , SS_{bet} , and SS_{w} that are easier to use than using deviations from means,

but they do not provide you with a basic understanding of ANOVA (see King and Minium, 2008). (It is these formulas that allow you to compute F without ever having calculated a single mean.) It is customary to place the results in a summary table, often called an ANOVA table:

Source	SS	df	s^2	F
Between groups	1365	2	682.5	13.571
Within groups	1357.8	27	50.29	
Total	2722.8	29		

Be sure to place between groups first, above within groups, to set up the proper ratio. As a check on your work, SS_{bet} plus SS_{w} should equal SS_{total} , and df_{bet} plus df_{w} should equal df_{total} (s^2_{w} plus s^2_{bet} do not equal s^2_{total}).

In order to determine if our obtained value of F is statistically significant, we must use a table for the F distribution, found in any introductory statistics textbook. The table gives critical values of F . When our obtained value of F is equal to or greater than the critical value, it indicates that our result is statistically significant (i.e., has a low probability of occurring by chance). The F distribution varies as a function of df_{bet} and df_{w} . Critical values of F are found at the intersection of df for the numerator (2 in our example) and df for the denominator (27 in our example), and in this case the critical values are 3.35 for $\alpha = 0.05$ and 5.49 for $\alpha = 0.01$. Thus, in our example, the probability of a type I error was less than 0.01, that is, the result is statistically significant. In addition to your F statistic and p -value, you should also provide a measure of effect size when reporting results. One commonly used measure for independent-groups ANOVA is omega-squared ($\hat{\omega}^2_{\text{bet}}$) (see King and Minium, 2008). It gives us a population-based, rather than a sample-based, estimate of how much of the proportion of the variance in the dependent variable was attributed to the different levels of treatment.

Interpreting a Significant F Value

Independent-groups ANOVA can be used with two samples, in which case F is the square of the t -statistic that compares the two sample means. A statistically significant result indicates that one population mean is either less than or greater than the other. What does it mean when we obtain a statistically significant value of F for three or more samples? In this case it tells us only that there is a difference among the populations. It does not tell us the manner in which they differ. For three groups, all three population means could be different from one another, or one could be greater than the other two, etc. To determine which means are significantly different from others, we normally use *post hoc* (*a posteriori*) comparisons. Some of the most commonly used tests are Duncan's multiple-range test, the Newman-Keuls test, Tukey's HSD test,

and the Scheffé test. Duncan's test is the least conservative with regard to type I error and the Scheffé test is the most conservative. An explanation of these tests is beyond the scope of this article, but most textbooks will provide a full explanation of one or more of them. However, before you can use any of them you must first have obtained a significant value of F . In our example, all four *post hoc* tests would reveal that teaching method 2 is superior to the other two methods, which did not significantly differ from one another.

There are some underlying assumptions associated with the use of ANOVA. The first is that the populations from which the samples are drawn are normally distributed. Moderate departure from the normal bell-shaped curve does not greatly affect the outcome, especially with large-sized samples (Glass *et al.*, 1972). However, results are much less accurate when populations of scores are very skewed or multimodal (Tomarken and Serlin, 1986), which is frequently the case in the behavioral sciences (Micceri, 1989). In this case, you should consider using the Kruskal-Wallis test, an assumption-freer (nonparametric) test for the independent-groups design (see King and Minium, 2008). This is especially true when using small samples. A second assumption is that of homogeneity of variance, that is, the variances in the populations from which samples are drawn are the same. However, this is a major problem only when variances differ considerably, and is less of a problem if you use samples that are of the same size (Milligan *et al.*, 1987; Tomarken and Serlin, 1986).

The Repeated-Measures Design

ANOVA can also be used with the repeated-measures design (e.g., testing the same subjects under two or more conditions). The major difference from the independent-groups design is that SS_{w} is partitioned into two parts: (1) SS_{subjects} , which is a reflection of the variability in scores resulting from individual differences, and (2) SS_{residual} , a reflection of the variability in scores due to chance. Although three variance estimates can be calculated (s^2_{subjects} , s^2_{bet} , and s^2_{resid}), normally we are interested only in the F ratio $s^2_{\text{bet}}/s^2_{\text{resid}}$ to determine if there is a statistically significant difference among groups. (We are usually not interested in whether or not individuals differ.)

Two-Way ANOVA

In the previous example, we examined the effects of three different teaching methods on mathematics achievement scores using an independent-groups design. There was only one treatment variable – teaching method. However, ANOVA allows us to study two or more treatment variables (called factors) simultaneously. Suppose, for example, that

we were also interested in whether the amount of time devoted to teaching mathematics affected achievement scores. Rather than conducting two separate studies, we can study both factors (teaching method and time spent teaching) simultaneously using a two-factor ANOVA design. If we study all three teaching methods (referred to as levels of the factor teaching method) and two different durations of time spent teaching (two levels; e.g., 45 min per day vs. 90 min), we have a 3×2 design. Let us suppose that we select eight students randomly for each of the six independent conditions (standard teaching method for 45 min per day, standard teaching method for 90 min per day, etc.) and after 1 year we obtain the following mathematics achievement scores:

Teaching method

Teaching time per day	Standard method	Method 2	Method 3	
45 min	60	73	62	$\bar{X}_{45} = 72.67$
	80	87	74	
	68	76	63	
	72	84	73	
	64	83	64	
	76	77	72	
	69	81	67	
	71	79	69	
90 min	$\bar{X} = 70$	$\bar{X} = 80$	$\bar{X} = 68$	$\bar{X}_{90} = 80.67$
	65	92	63	
	81	106	77	
	68	103	70	
	78	95	68	
	70	97	70	
	76	101	72	
	72	99	67	
	74	99	73	$\bar{X} = 76.67$
	$\bar{X} = 73$	$\bar{X} = 99$	$\bar{X} = 70$	
	$\bar{X}_{\text{std}} = 71.5$	$\bar{X}_2 = 89.5$	$\bar{X}_3 = 69$	

The six combinations of rows and columns are called cells. The six cell means, two row means, three column means, and the grand mean are provided. In two-way ANOVA we want to know if there is a main effect for any of the factors, or, in other words, if there are differences in the means of the levels of one factor averaged across the levels of the other factor. In our example, there are two possible main effects and the essential questions can be phrased as: (1) Is there an overall influence of teaching method (for both the 45-min and 90-min conditions), and (2) is there an overall influence of time devoted to teaching (across all three teaching methods)?

There is an equally, if not more, important question that we can examine with a factorial design: Is there an interaction effect – are the differences among the levels of one factor the same for all levels of the other factor? To

Figure 1 Hypothetical scores in a 3×2 factorial study of the effects of teaching method and time spent teaching on mathematics achievement scores.

better understand this, let us first look at the results of our study in graph form (Figure 1).

In our hypothetical study, if an increase in time spent teaching mathematics had an equal effect for all three teaching methods, the three lines would be parallel. A sizable gap between the lines indicates a possible main effect for teaching method. In our graph, we see evidence for a main effect, but the difference between method 2 and the other two teaching methods depends on the amount of time it is used in the classroom. Method 2 results in moderately better mathematics achievement scores when used for 45 min per day, but dramatically better scores when students are taught mathematics by this method for 90 min per day. If there had been a main effect for teaching method (method 2 better than the other two) without an interaction effect, the differences between method 2 and the others would have been the same for both levels of the other factor (teaching time per day). A significant interaction effect tells us that before we can interpret the effects of a factor, we must examine that factor at each level of the other factor. This will, of course, involve examining cell means. Three-factor experimental designs (e.g., teaching method \times time spent teaching \times gender) and even higher-order designs are possible, but interpretation of interaction effects becomes more difficult.

When calculating two-way ANOVA, SS_{total} is partitioned into four parts. SS_{wc} (within cell) is the equivalent of SS_{w} (within groups) in the one-factor design. SS_{bet} is split into three parts: SS_{rows} , SS_{columns} , and $SS_{\text{rows} \times \text{columns}}$. To see how to calculate two-way ANOVA, see King and Minium (2008). In our example, we obtain a significant

effect for rows ($F = 30.78$, $df = 1/42$, $p < 0.001$), columns ($F = 80.21$, $df = 2/42$, $p < 0.001$), and rows \times columns interaction ($F = 14.59$, $df = 2/42$, $p < 0.001$). As at least one of our main effects was statistically significant, we may now conduct a *post hoc* test to see which levels differed from the others (e.g., method 2 vs. the other two).

Planned Comparisons

When conducting any statistical test one wants the test to have considerable power, that is, a high probability of rejecting a false null hypothesis. *Post hoc* tests allow us to make all possible pair-wise comparisons, but to protect us from making type I errors, the differences between means must be large enough to be declared statistically significant. If one's study is exploratory in nature, then ANOVA is a very good statistical test. However, if one knows in advance of conducting a study which comparisons are important to him or her, one should use planned (*a priori*) comparisons in place of ANOVA and *post hoc* comparisons (Rosnow and Rosenthal, 1989; Wilkinson *et al.*, 1999; Winer *et al.*, 1991). To do so, one should conduct independent-groups *t* tests using s^2_w (calculated from all groups), but to protect against type I errors, all the comparisons must be orthogonal (unique, with no overlap). When comparing k groups, there are only $k-1$ orthogonal comparisons. In our example, we might be interested in the two comparisons standard method versus (method 2 + method 3) and method 2 versus method 3. Unlike *post hoc* comparisons, one does not need a significant overall F in order to use planned comparisons. Even Ronald Fisher recognized the value of planned comparisons:

When the [F] test does not demonstrate significant differentiation, much caution should be used before claiming

significance for special comparisons. Comparisons, which the experiment was designed to make, may, of course, be made without hesitation (Fisher, 1949: 57).

Bayesian Statistical Analysis

Introduction

Bayesian statistics has been considered, for quite a long time, as a branch of statistics; however, its role in the development of statistical inference is much more profound than that. Its philosophical base traces back to the very initial and rather subjective interpretation of the notion of probability and its use in everyday human activities. It is related with the notion of ‘pithanon,’ as used by Carneades (214–129/8 BC), meaning persuasive, convincing, which allows human beings to take decisions and act without necessarily having perfect knowledge of the situation and conditions they are facing. For a detailed account on Carneades’ philosophical position, the reader is referred to Bett (1989).

According to the Bayesian approach to statistics, statistical inference is not just about collecting, analyzing, and interpreting data that have an endogenous variability, which is the frequentist view of statistics. Rephrasing de Finetti (1974, 1975), it is about developing a plausible way of studying uncertain events through the notion of probability. It also provides a coherent methodology for inductive mathematical reasoning when new information is available. In short, statistics is the study of uncertainty.

Savage (1954) and Lindley (1965, 2000) state that the only self-consistent (coherent) way to deal with uncertainty is by expressing it through the notion of probability. When dealing with a statistical problem, uncertainty refers to data, parameters, and models. Having expressed the uncertainty about these, the rest concerns taking into account the information provided by the data and updating the uncertainty according to the rules of probability calculus. The basic mathematical tool to do it is provided by the Bayes’ theorem. Thus, the Bayesian approach provides a unified and coherent inferential procedure.

It must be mentioned here that the rules of probability calculus, namely: (a) the addition rule (finite or countable), (b) the product rule, and (c) the convexity rule (that the probability lies in the convex unit interval taking the value 1 for the sure event), have to be demonstrated on the basis of axioms about the logical and, at the same time, subjective human behavior in an uncertain environment. There exist several axiomatic systems resulting in the above three probability rules. For a discussion of such axiomatic systems, see Savage (1954), DeGroot (1970), and Fishburn (1986).

The Bayesian approach, although quite simple in principle, is often quite demanding, especially when dealing

with complicated and highly structured statistical models. There are two main tasks to be accomplished: (a) modeling uncertainty about the probabilistic behavior of the statistical data at hand and the parameters involved, including models, and (b) applying very efficient computational methods in order to estimate the parameters and confirm the models. Regarding the first task, much of the statistical work is based on the notions of coherence and exchangeability (both due to de Finetti (1937)), and it is greatly simplified by using the so-called objective priors (diffuse, flat, reference or noninformative priors). Regarding the second, the development of modern and quite efficient computational techniques, such as Markov-chain Monte Carlo (MCMC), has made this task a rather straightforward procedure. Their versatility had an enormous impact on the Bayesian approach and its spread in many disciplines during the last two decades.

Bayesian Inference

We express the uncertainty about getting a data value x related with a population parameter θ , both x and θ being in general multivariate. This is achieved by a critical choice of a joint distribution for x and θ , conditional on the state of knowledge we have at this moment about the population under study. An expert opinion, familiar with the specific population, might be very helpful in making such a choice. Specifically, the task is to choose a probability density $p(x, \theta|K)$ (with respect to Lebesgue or counting measure), where K represents the present state of knowledge. In a more general setup, K might also include a set of modeling assumptions and random hyperparameters. In general, given the state of knowledge K , it is more convenient to choose separately the densities $p(x|\theta, K)$ and $p(\theta|K)$, and then apply the product rule to get

$$p(x, \theta|K) = p(x|\theta, K)p(\theta|K) \quad [1]$$

The product rule again allows us to write the density $p(x, \theta|K)$ in the form

$$p(x, \theta|K) = p(\theta|x, K)p(x|K) \quad [2]$$

and thus, combining the above two results, we have

$$p(\theta|x, K) = p(x|\theta, K)p(\theta|K)/p(x|K) \quad [3]$$

If we apply now the addition rule on both sides of [1], with x fixed, we conclude that

$$p(x|K) = \int p(x|\theta, K)p(\theta|K)d\theta$$

and, thus, introducing the latter result into [3], we get the Bayes' formula (Bayes, 1763)

$$p(\theta|x, K) = \frac{p(x|\theta, K)p(\theta|K)}{\int p(x|\theta, K)p(\theta|K)d\theta} \quad [4]$$

The denominator, either as $p(x|K)$ or under the integral form $\int p(x|\theta, K)p(\theta|K)d\theta$, is called the predictive distribution for x . It does not convey any information about the parameter θ (as far as a data value x does not raise doubts about the state of knowledge K itself) and, thus, it acts as a normalizing constant. For simplicity in the notation, the reference to the state of knowledge K is also omitted. We may then write the Bayes' formula [4] as follows:

$$p(\theta|x) \propto p(\theta)p(x|\theta) \quad [5]$$

Formula [5] allows us to go from $p(x|\theta)$ to $p(\theta|x)$; thus, it is also known as the inverse probability law.

The first factor on the right hand side (RHS) of [5] is called a prior, since it expresses the information we have about the parameter θ prior to receiving the data value x . The conditional density $p(\theta|x)$ expresses the updated, according to the Bayes' theorem, distribution of θ after receiving the data value x . Thus, it is the posterior, with reference to x , distribution of θ .

In practice, instead of a single data value x , we have a random sample $\{x_i, i = 1, \dots, n\}$, denoted for simplicity by $x^{(n)}$. Then, $p(x^{(n)}|\theta) = \prod_{i=1}^n p(x_i|\theta)$, and the Bayes' formula takes the form

$$p(\theta|x^{(n)}) \propto p(\theta) \prod_{i=1}^n p(x_i|\theta)$$

The product $\prod_{i=1}^n p(x_i|\theta)$, considered as a function of the parameter θ , is called the likelihood and is denoted by $L(\theta, x^{(n)})$.

The above posterior can be used as the prior for a second dataset $x^{(n^*)} = \{x_{n+i}, i = 1, \dots, n^*\}$. Indeed, the posterior distribution of parameter θ , given the whole dataset $x^{(n+n^*)} = \{x_{n+i}, i = 1, \dots, n+n^*\}$, is

$$p(\theta|x^{(n+n^*)}) \propto p(\theta) \prod_{i=1}^{n+n^*} p(x_i|\theta) \propto p(\theta|x^{(n)}) \prod_{i=1}^{n^*} p(x_{n+i}|\theta)$$

Thus, the posterior of θ , given the first dataset $x^{(n)} = \{x_i, i = 1, \dots, n\}$, is the prior for the next dataset $x^{(n^*)} = \{x_{n+i}, i = 1, \dots, n^*\}$, and so on.

Quite often, the involved parameter θ consists of two parts, namely, $\theta = (\zeta, \eta)$, where the parameter ζ is the one of interest, whereas the parameter η is a nuisance parameter. In such a case, we only have to integrate out the nuisance parameter η from the joint posterior of $\theta = (\zeta, \eta)$. Specifically, the posterior of the parameter of interest ζ is

$$p(\zeta|x^{(n)}) = \int p(\zeta, \eta|x^{(n)})d\eta$$

usually called marginal posterior.

Exchangeability

It is essential to give an explanation about how the prior for a parameter θ emerges. The answer has been given by de Finetti's theorem (de Finetti, 1937), which constitutes the backbone of the Bayesian statistics. The basic notion here is that of exchangeability.

The random variables X and Y are called exchangeable if

$$\begin{aligned} F(x, y) &= P[X \leq x, Y \leq y] = P[Y \leq x, X \leq y] \\ &= F(y, x) \text{ for all } (x, y) \in \mathbb{R}^2 \end{aligned}$$

This means that the pair (X, Y) is distributed as the pair (Y, X) and, thus, the order does not matter. Similarly, a finite sequence of random variables, $\{X_i, i = 1, 2, \dots, n\}$ is called exchangeable if any permutation, $(X_{i_1}, \dots, X_{i_n})$ say, is distributed as (X_1, \dots, X_n) . The notion of exchangeability is then extended to an infinite sequence of random variables $\{X_n, n = 1, 2, \dots\}$, say, by requiring that every finite subsequence of it is exchangeable.

Let now $\{X_n, n = 1, 2, \dots\}$ be an infinite sequence of binary random variables, each one of which is taking the value 1 or 0 according to the realization of an event (a success) or not (a failure). Suppose we make the statement that for any $n \in \mathbb{N}$, the probability to have k successes in any subsequence of length n of X 's, $\{X_{i_1}, \dots, X_{i_n}\}$, say, depends only on k and n . In other words, we assume that the random variables X_n ($n = 1, 2, \dots$) are exchangeable. Let $P_{k,n}$ denote the above probability, that is,

$$P_{k,n} = P\left[\sum_{j=1}^n X_{i_j} = k\right], k = 0, 1, \dots, n \quad (n = 1, 2, \dots)$$

Then, the above statement of exchangeability of X 's is tantamount to the following:

There exists a probability measure Π over the interval $[0, 1]$ such that

$$\begin{aligned} P_{k,n} &= \binom{n}{k} \int_0^1 \theta^k (1-\theta)^{n-k} \Pi(d\theta) \\ &= \binom{n}{k} \int_0^1 \theta^k (1-\theta)^{n-k} \pi(\theta) d\theta, \\ k &= 0, 1, \dots, n \quad (n = 1, 2, \dots) \end{aligned}$$

where $\pi(\theta)$ denotes the density of the parameter θ , which represents the unknown probability of success (here, π is the derivative of Π with respect to Lebesgue or counting measure over the interval $[0, 1]$).

Thus, the existence of a prior distribution $\pi(\theta)$, for the probability of success θ , does not arise out of nothing, but it is a consequence of our general statement about X 's, that is, that of exchangeability. In de Finetti (1937), a generalization of the above exchangeability result for random variables taking values in \mathbb{R}^d has also been derived. Parametric, together with nonparametric, versions of de Finetti's theorem can be found in Diaconis and Freedman (1980) and in Bernardo and Smith (1994). Specifically, under additional assumptions of minor importance, when the random variables X_m ($m = 1, 2, \dots$) are exchangeable, there exists a parametric function $F(x|\theta)$ with $\theta \in \Theta$ such that the joint distribution Q of X_i ($i = 1, 2, \dots, m$) has the following form:

$$Q(x_1, \dots, x_m) = \int_{\Theta} \left\{ \prod_{i=1}^m F(x_i|\theta) \right\} \pi(\theta) d\theta, m = 1, 2, \dots$$

It is obvious that the converse statement is true in all the above cases.

Exponential Family and Conjugate Priors

A density $p(x|\theta)$ belongs to the exponential family if it can be written as follows:

$$\begin{aligned} p(x|\theta) &= f(x)g(\theta)\exp\left\{\sum_{j=1}^k \varphi_j(\theta)b_j(x)\right\} \\ &= f(x)g(\theta)\exp\left\{\varphi(\theta)^T b(x)\right\}, \\ x &\in \mathcal{X} \subset \mathbb{R}^d \text{ and } \theta \in \Theta \subset \mathbb{R}^m \end{aligned} \quad [6]$$

Then, the conjugate prior for the parameter θ is of the form

$$\begin{aligned} p(\theta) &\propto \{g(\theta)\}^\eta \exp\left\{\sum_{j=1}^k v_j \varphi_j(\theta)\right\} \\ &= \{g(\theta)\}^\eta \exp\{\mathbf{v}^T \varphi(\theta)\}, \theta \in \Theta \end{aligned} \quad [7]$$

with parameters (hyperparameters) η and $\mathbf{v} = (v_1, \dots, v_k)^T$.

We see, therefore, that when $p(x|\theta)$ belongs to the exponential family, so does its conjugate prior $p(\theta)$. Conjugate priors, although restrictive sometimes, have the advantage of great mathematical simplicity in deriving posteriors in closed form. An additional advantage is that limiting versions of conjugate priors correspond to the so-called objective priors. Objective priors are most often improper, since their integral over the whole parameter space is not equal to one. They are, therefore, incoherent, meaning that they do not satisfy the probability axioms. Despite this fact, their posteriors can be proper, and, thus, coherent. Objective priors play a very important role in objective Bayesian statistics.

Let now $\mathbf{x}^{(n)} = \{\mathbf{x}_i, i = 1, \dots, n\}$, be a random sample from [6]. The likelihood for the parameter θ is then

$$\begin{aligned} L(\theta, \mathbf{x}^{(n)}) &= \prod_{i=1}^n p(x_i|\theta) \propto \{g(\theta)\}^n \exp\left\{\sum_{j=1}^k \varphi_j(\theta) \left[\sum_{i=1}^n b_j(x_i)\right]\right\} \\ &= \{g(\theta)\}^n \exp\left\{\varphi(\theta)^T \mathbf{t}(\mathbf{x}^{(n)})\right\} \end{aligned}$$

where $\mathbf{t}(\mathbf{x}^{(n)}) = (t_1(\mathbf{x}^{(n)}), \dots, t_k(\mathbf{x}^{(n)}))^T$ with

$$t_j(\mathbf{x}^{(n)}) = \sum_{i=1}^n b_j(x_i), j = 1, \dots, k$$

The quantity $\mathbf{t} = \mathbf{t}(\mathbf{x}^{(n)})$ is the sufficient statistic for θ , in other words, it conveys the same information about θ as the whole dataset $\mathbf{x}^{(n)}$.

Applying Bayes' theorem now, the posterior has the same form as the prior. Specifically:

$$\begin{aligned} p(\theta|\mathbf{x}^{(n)}) &\propto \{g(\theta)\}^{\eta+n} \exp\left\{\sum_{j=1}^k \varphi_j(\theta) \left[v_j + \sum_{i=1}^n b_j(x_i)\right]\right\} \\ &= \{g(\theta)\}^{\eta+n} \exp\left\{\varphi(\theta)^T [\mathbf{v} + \mathbf{t}(\mathbf{x}^{(n)})]\right\} \\ &= \{g(\theta)\}^{\eta_n} \exp\left\{\varphi(\theta)^T \mathbf{v}_n\right\}, \theta \in \Theta \end{aligned}$$

with updated parameters, namely, $\eta_n = \eta + n$ and $\mathbf{v}_n = \mathbf{v} + \mathbf{t}(\mathbf{x}^{(n)})$.

In almost all textbooks on Bayesian statistics, there are extensive tables and results for priors within the exponential family together with their marginal posteriors, predictive distributions, and their limiting objective forms, cf. DeGroot (1970), Aitchison and Dunsmore (1975), Robert (2001), Gelman et al. (2003) and Press (2003).

Bayesian Statistical Methods

Bayesian Decision-Making

Having derived the posterior for a parameter θ , all information we have about it is included in $p(\theta|\mathbf{x}^{(n)})$. Thus, if we have to take a decision, the consequences of which are related with the true value of θ , it is logical to make best use of the information we have about it, that is, to make use of $p(\theta|\mathbf{x}^{(n)})$. Within the decision-making context, the parameter θ represents the state of nature, whereas the decision to be taken is called the action and denoted by α . The set of all actions under consideration is denoted by \mathcal{A} . The loss implied by taking an action α , when the true state of nature is θ , is defined by a loss function $L(\alpha, \theta)$, usually bounded from below. Since the true state of nature θ is not known, associated with an action α is the Bayes' expected loss

$$R(\alpha) = E[L(\alpha, \theta)|\mathbf{x}^{(n)}] = \int_{\Theta} L(\alpha, \theta) p(\theta|\mathbf{x}^{(n)}) d\theta \quad [8]$$

It must be mentioned that when the action α affects the distribution of the parameter θ , the above expectation has to be with respect to $p(\theta|\alpha, \mathbf{x}^{(n)})$. According to the above setup,

the best action is that associated with the lowest Bayes' expected loss. Thus, a decision α^* is optimal if and only if

$$R(\alpha^*) = \inf\{R(\alpha) : \alpha \in \mathcal{A}\}$$

Such an action α^* is then called the Bayes' action. In general, α^* constitutes the Bayes' rule. For an extensive presentation of statistical decision theory, see DeGroot (1970), Berger (1985), and Lindley (1985).

Parameter Estimation

When in place of the action space \mathcal{A} we have the parameter space Θ , then an action is a choice of a particular value, say $\tilde{\theta}$, for the parameter θ . In other words, the Bayesian estimation problem is a decision problem, where the Bayes' rule gives the optimal estimate for θ , under the considered loss function $L(\tilde{\theta}, \theta)$. According to [8], the Bayes' estimate for θ is the quantity minimizing the posterior expected risk:

$$R(\tilde{\theta}) = E[L(\tilde{\theta}, \theta) | x^{(n)}] = \int_{\Theta} L(\tilde{\theta}, \theta) p(\theta | x^{(n)}) d\theta \quad [9]$$

It can be easily shown that with the quadratic loss function $L(\tilde{\theta}, \theta) = \|\tilde{\theta} - \theta\|^2$, the optimal estimate for θ is its posterior mean, namely, $E(\theta | x^{(n)})$. Thus, we have

$$\begin{aligned} E[\theta | x^{(n)}] &= \underset{(\theta \in \Theta)}{\operatorname{argmin}} R(\tilde{\theta}) \\ &= \underset{(\theta \in \Theta)}{\operatorname{argmin}} \int_{\Theta} \|\tilde{\theta} - \theta\|^2 p(\theta | x^{(n)}) d\theta \end{aligned}$$

It is well known that the class of loss functions $L(\tilde{\theta}, \theta)$ for which the Bayes' estimate of a parameter θ coincides with the posterior mean, is very large. In fact, any loss function that belongs to the class of Bregman divergences has this property. The converse is also true. For the definition and applications of Bregman Divergences in statistics, see Kokolakis *et al.* (2006).

Estimation of the multinomial parameter

Let Y be a discrete random variable taking values from the set $\{1, 2, \dots, m\}$ with probabilities θ_j ($j = 1, \dots, m$), where $\sum_{j=1}^m \theta_j = 1$. In what follows, for notational convenience, we introduce an m -variate random vector $X = (X_1, \dots, X_m)$ such that $X_j = 1$ when $Y = j$ and $X_j = 0$ otherwise ($j = 1, \dots, m$). Then, the probability distribution of X , given the parameter θ , can be written as follows:

$$\begin{aligned} p(x | \theta) &= \prod_{j=1}^m \theta_j^{x_j} = \exp \left\{ \sum_{j=1}^m x_j \log \theta_j \right\}, x_j \in \{0, 1\} \quad [10] \\ &\text{with } \sum_{j=1}^m x_j = 1 \text{ and} \\ \theta \in S^m &= \left\{ \theta \in \mathbb{R}^m : \theta_j \geq 0 \ (j = 1, \dots, m) \text{ with } \sum_{j=1}^m \theta_j = 1 \right\} \end{aligned}$$

The set S^m above is known as the $(m-1)$ -simplex.

Thus, the multinomial distribution is apparently within the exponential family and its conjugate prior is of the form

$$p(\theta) = k \cdot \prod_{j=1}^m \theta_j^{\alpha_j - 1}, \theta \in S^m \text{ with } \alpha_j > 0 \ (j = 1, \dots, m) \quad [11]$$

known as the Dirichlet distribution and denoted by $D(\alpha)$. The normalizing constant k above is given by

$$\begin{aligned} k &\equiv k(\alpha) = \left\{ \int_{S^m} \prod_{j=1}^m \theta_j^{\alpha_j - 1} d\theta \right\}^{-1} \\ &= \frac{\Gamma(\alpha)}{\Gamma(\alpha_1) \dots \Gamma(\alpha_m)} \text{ with } \alpha = \sum_{j=1}^m \alpha_j \end{aligned} \quad [12]$$

where

$$\Gamma(\alpha) = \int_0^\infty t^{\alpha-1} e^{-t} dt, \alpha > 0$$

is the gamma function, satisfying the following recursive relation:

$$\Gamma(\alpha + 1) = \alpha \Gamma(\alpha) \text{ for } \alpha > 0 \text{ with } \Gamma(1) = 1$$

Note that the flat noninformative prior corresponds to taking: $\alpha_1 = \alpha_2 = \dots = \alpha_m = 1$.

It can be easily seen that in order to find the mean of the above distribution, a renormalization procedure has to be applied and, thus, the mean will be expressed as the ratio of two normalizing constants. The same is true for any moment of the above distribution. Specifically, with $\nu = (\nu_1, \nu_2, \dots, \nu_m)^T$, we have

$$E \left[\prod_{j=1}^m \theta_j^{\nu_j} \right] = \frac{k(\alpha)}{k(\alpha + \nu)}, \nu_j = 0, 1, 2, \dots \ (j = 1, \dots, m)$$

and, thus,

$$\begin{aligned} E[\theta_j] &= \frac{\alpha_j}{\alpha}, \operatorname{Var}[\theta_j] = \frac{\alpha_j (\alpha - \alpha_j)}{\alpha^2 (\alpha + 1)}, \text{ and} \\ \operatorname{Cov}[\theta_j, \theta_k] &= -\frac{\alpha_j \alpha_k}{\alpha^2 (\alpha + 1)}, \ (j \neq k) \end{aligned} \quad [13]$$

Let $x^{(n)} = \{x_i, i = 1, \dots, n\}$ be a random sample from the multinomial distribution [10]. Then, the likelihood function is

$$L(\theta, x^{(n)}) = p(x^{(n)} | \theta) = \prod_{i=1}^n p(x_i | \theta) = \prod_{j=1}^m \theta_j^{n_j}$$

where $\mathbf{n} = (n_1, \dots, n_m)^T$ with $n_j = \sum_{i=1}^n x_{ij}$, $j = 1, \dots, m$, the sufficient statistics for the multinomial parameter θ , and $\sum_{j=1}^m n_j = n$. Multiplying by the prior [11], we get

$$p(\theta | x^{(n)}) = k(\alpha^{(n)}) \prod_{j=1}^m \theta_j^{\alpha_j^{(n)} - 1}, \theta \in S^m$$

where $k(\alpha^{(n)})$ is as in [12] with updated parameters $\alpha^{(n)} = \alpha + \mathbf{n}$ and $\alpha^{(n)} = \alpha + n$.

Using the quadratic loss function, the optimal estimate for θ is its posterior mean. With the updated parameter $\alpha^{(n)}$, the first result in [13] implies that

$$E[\theta_j | \mathbf{x}^{(n)}] = \alpha_j^{(n)} / \alpha^{(n)} = \frac{\alpha_j + n_j}{\alpha + n}, j = 1, \dots, m \quad [14]$$

It is interesting to write the posterior mean in the following form:

$$E[\theta | \mathbf{x}^{(n)}] = \frac{\alpha}{\alpha + n} \times E[\theta] + \frac{n}{\alpha + n} \times \bar{X}_n \quad [15]$$

that is, the posterior mean of θ is a convex combination of the prior mean $E[\theta]$ and its sample mean \bar{X}_n .

The mean squared errors of the above estimates are given by the associated risks, which, with the quadratic loss function used here, coincide with the posterior variances. Thus, using the second result in [13], we have

$$\begin{aligned} \text{Var}[\theta_j | \mathbf{x}^{(n)}] &= \frac{\alpha_j^{(n)} (\alpha_j^{(n)} - \alpha_j^{(n)})}{\alpha_n^2 (\alpha_n + 1)} \\ &= \frac{(\alpha_j + n_j)(\alpha - \alpha_j + n - n_j)}{(\alpha + n)^2 (\alpha + n + 1)} \\ &(\rightarrow 0 \text{ as } n \rightarrow \infty) (j = 1, \dots, m) \end{aligned} \quad [16]$$

It is obvious, therefore, that when the quantity $\alpha = \sum_{j=1}^m \alpha_j$ is very small compared to the sample size $n = \sum_{j=1}^m n_j$, the above estimates of the components of the parameter vector θ are almost equal to their frequentist estimates and they agree completely when $\alpha_j = 0$ ($j = 1, \dots, m$). Such a choice of hyperparameter values implies an improper prior that nevertheless has a proper posterior provided that $n_j \geq 1$ ($j = 1, \dots, m$).

In addition, from the limiting behavior of the above estimates (cf. [14]–[16]), we conclude that, under the assumption of the exchangeability of X 's, as $n \rightarrow \infty$, the posterior mean of the parameter θ will coincide with its actual value, whatever it is.

A remarkable property of the Dirichlet family of priors is the following.

Let θ be Dirichlet distributed with parameter vector α . With $l < m$, let $I = \{I_1, \dots, I_l\}$ be a partition of the set $\{1, \dots, m\}$ and $\varphi_i = \sum_{j \in I_i} \theta_j$ ($i = 1, \dots, l$). Then, the random vector $\varphi = (\varphi_1, \dots, \varphi_l)^T$ is Dirichlet distributed with parameter vector $\beta = (\beta_1, \dots, \beta_l)^T$, where $\beta_i = \sum_{j \in I_i} \alpha_j$ ($i = 1, \dots, l$).

We conclude, therefore, from the above result that the requirement for coherence does not allow the use of objective flat $D(1, \dots, 1)$ priors for both the parameters θ and φ .

From the above result, it is obvious that the marginal distribution of $\theta \equiv \theta_1$ is the univariate Dirichlet with parameters $\alpha = \alpha_1$ and $\beta = \sum_{j=2}^m \alpha_j$, known as the $Beta(\alpha, \beta)$ distribution. When dealing with binomial data, a reasonable choice for the hyperparameter values α and β

could be $\alpha = \beta = 1$, resulting in the flat noninformative prior

$$p(\theta) = 1, 0 \leq \theta \leq 1$$

The above prior had been used by both Bayes (1763) and Laplace (1785) in their demonstration of the inverse probability law, of which Laplace was aware independently of Bayes.

Application

For demonstration purposes, we present the following application. We analyze the data in Table 1 which refer to the grades (response variable) of a random sample of first-year successful university students in relation to the parents' educational level (explanatory variable).

We have here three cell probability vectors, namely, $\theta_i = (\theta_{i1}, \theta_{i2}, \theta_{i3})$ ($i = 1, 2, 3$), corresponding to the three categories of parents' educational level. We assume that the parameters θ_1 , θ_2 , and θ_3 are independent, Dirichlet distributed with a common hyperparameter vector $\alpha = (\alpha_1, \alpha_2, \alpha_3)$.

With N the 3×3 matrix representing the above contingency table and θ the 3×3 matrix representing the corresponding cell probabilities, the likelihood function is

$$L(\theta, N) \propto \prod_{i=1}^3 \prod_{j=1}^3 \theta_{ij}^{n_{ij}}$$

Thus,

$$p(\theta | N) \propto p(\theta) p(N | \theta) \propto \prod_{i=1}^3 \prod_{j=1}^3 \theta_{ij}^{\alpha_i + n_{ij} - 1}$$

and, therefore,

$$p(\theta | N) = \prod_{i=1}^3 D(\theta_i | \alpha_i + n_i) \quad [17]$$

We conclude, therefore, that the cell probability vectors θ_i ($i = 1, 2, 3$), conditional on N , are again independent, Dirichlet distributed with updated hyperparameter vectors $\alpha_i^{(n)} = \alpha + n_i$ ($i = 1, 2, 3$), respectively.

For the common hyperparameter vector α , we assume that its components α_1 , α_2 , and α_3 are all equal to 1,

Table 1 Numbers of first-year successful university students according to grades received and parents' educational level

Parents' educational level	Grades		
	A	B	C
Elementary	3	32	50
Secondary	7	59	63
University	8	93	134

Figure 1 Posterior distributions for cell probabilities θ_{ij} ($i, j = 1, 2, 3$). Continuous lines for elementary parents' educational level ($i = 1$), dashed lines for secondary level ($i = 2$), and dot lines for university level ($i = 3$).

implying an objective flat prior for each one of the parameter vectors θ_i ($i = 1, 2, 3$). Their posterior distributions, as defined by [17], are presented in **Figure 1**. The three cases (a), (b), and (c) correspond to the grade categories A, B, and C, respectively. Specifically, in case (a), we have the posteriors of the cell probabilities θ_{i1} ($i = 1, 2, 3$); in case (b), those of the cell probabilities θ_{i2} ($i = 1, 2, 3$); and in case (c), those of the cell probabilities θ_{i3} ($i = 1, 2, 3$). Comparing the three graphs within each grade category, we may realize that there is no serious discrepancy between the posterior distributions, apart from the fact that the parents' category secondary education, presented with dashed lines, shows a slightly better response (higher located posteriors for A and B grades combined with a lower located posterior for C grades). For sensitivity analysis, several values for the components of the hyperparameter α have been considered in the range (0.5, 5.0), with step 0.5, and all were found to be in agreement with the above conclusion.

Alternative methods for analyzing contingency tables are based on Hierarchical models and generalized linear model (cf. Gelman *et al.*, 2003). For a rather extensive presentation of Bayesian models in educational research, see Novick and Jackson (1974) and Bock (1989).

Interval Estimation

For a scalar parameter θ whose posterior $p(\theta | x^{(n)})$ can be found in closed form, it is a rather easy task to find an interval (a, b) such that

$$F(a) = 1 - F(b) = \frac{1}{2}(1 - \beta) \quad [18]$$

where

$$F(a) = P[\theta \leq a | x^{(n)}] = \int_{-\infty}^a p(\theta | x^{(n)}) d\theta$$

and β a prespecified number in the interval (0, 1). Such a region is called the credibility interval for the parameter θ

with credibility level β . This credibility interval is not necessarily the shortest one. In order to be the shortest, it has to contain the highest posterior density values. Then, it is called the highest posterior density credibility interval. It is obvious that, when the posterior is unimodal and symmetric, the credibility interval defined by [18] coincides with the shortest one. Usually, we simulate data from the posterior $p(\theta | x^{(n)})$ using MCMC methods. Then, we only have to discard the most extreme values at appropriate equal proportions, and the region which is covered by the remaining data, is the required credibility interval.

Hypothesis Testing

According to the Bayesian approach, the hypothesis-testing problem, either for simple (sharp) hypotheses or for composite hypotheses, can also be treated within a decision-theoretic context. It must be mentioned here that the hypothesis-testing problem is not of prime interest within the Bayesian approach, mainly because it oversimplifies the problem of inference by requiring an answer of type 'yes' or 'no'.

Suppose that the parameter space Θ is partitioned into two subsets, say Θ_0 and Θ_1 . Specifically, we assume: $\Theta = \Theta_0 \cup \Theta_1$ with $\Theta_0 \cap \Theta_1 = \emptyset$. Let the null hypothesis H_0 states that $\theta \in \Theta_0$ while the alternative H_1 states that $\theta \in \Theta_1$. Suppose, in addition, that the loss is zero when accepting the right hypothesis, while the loss implied by making a type-I error (rejecting the null hypothesis H_0 when it is true) is a multiple α of the loss implied by making a type-II error (rejecting the alternative hypothesis H_1 when it is true). Then, the Bayes' rule states the following:

$$\begin{aligned} \text{Reject } H_0 \text{ iff } & \frac{P[\Theta_1 | x^{(n)}]}{P[\Theta_0 | x^{(n)}]} \\ & = \int_{\Theta_1} p(\theta | x^{(n)}) d\theta / \int_{\Theta_0} p(\theta | x^{(n)}) d\theta > \alpha \end{aligned} \quad [19]$$

The above ratio is the posterior odds ratio against H_0 (and in favor of H_1).

Consider now two special cases.

Case a: Suppose that both the sets Θ_0 and Θ_1 are single-point sets, that is, $\Theta_0 = \{\theta_0\}$ and $\Theta_1 = \{\theta_1\}$, with prior probabilities π_0 and $\pi_1 = 1 - \pi_0$, respectively. Then, the Bayes' rule [19] becomes

$$\text{Reject } H_0 \text{ iff } \frac{\pi_1 p(\mathbf{x}^{(n)}|\theta_1)}{\pi_0 p(\mathbf{x}^{(n)}|\theta_0)} > \alpha$$

The ratio π_1/π_0 represents the prior odds ratio against H_0 , while the quantity

$$B(\mathbf{x}^{(n)}) = p(\mathbf{x}^{(n)}|\theta_1)/p(\mathbf{x}^{(n)}|\theta_0)$$

is called the Bayes' factor against H_0 . Thus, the Bayes' rule becomes:

$$\text{Reject } H_0 \text{ iff } \{\text{prior odds against } H_0\} \times \{\text{Bayes factor against } H_0\} > \alpha \quad [20]$$

Case b: Suppose that the null hypothesis is a simple one, say $H_0: \theta = \theta_0$, while the alternative is the composite one $H_1: \theta \neq \theta_0$. Suppose, as before, that the null hypothesis has a prior probability π_0 . Then, the alternative has a prior probability $\pi_1 = 1 - \pi_0$ and the Bayes' rule is

$$\text{Reject } H_0 \text{ iff } \pi_1 \int_{\Theta_1} p(\mathbf{x}^{(n)}|\theta) d\theta / \pi_0 p(\mathbf{x}^{(n)}|\theta_0) > \alpha$$

with $\Theta_1 = \Theta - \{\theta_0\}$.

It must be mentioned here that using positive probabilities for sharp hypotheses as the above was suggested by Jeffreys (1961).

Extensions

Mixtures of Models and Model Selection

Suppose that, according to our present state of knowledge K , there exists a set $\mathcal{M} = \{1, 2, \dots, M\}$ of possible models from one of which the random sample $\mathbf{x}^{(n)} = \{x_i, i = 1, \dots, n\}$ has been derived. Let M be the discrete random variable defining the actual model. Then, we have

$$p(\mathbf{x}^{(n)}) = \sum_{m=1}^M p(\mathbf{x}^{(n)}|m) p(m)$$

with

$$p(\mathbf{x}^{(n)}|m) = \int_{\Theta_m} p(\mathbf{x}^{(n)}|\theta_m, m) p(\theta_m|m) d\theta_m \quad (m = 1, \dots, M) \quad [21]$$

the predictive distribution of $\mathbf{x}^{(n)}$ when it comes from model m , and θ_m ($m = 1, \dots, M$), the model-specific parameters.

Applying Bayes' theorem, the model posterior probabilities will be

$$p(m|\mathbf{x}^{(n)}) \propto p(\mathbf{x}^{(n)}|m) p(m), \quad m = 1, \dots, M \quad [22]$$

with proportionality constant k defined by

$$k^{-1} = \sum_{m=1}^M p(\mathbf{x}^{(n)}|m) p(m)$$

The posterior odds for the model m against the model m' , say, are as follows:

$$\frac{p(m|\mathbf{x}^{(n)})}{p(m'|\mathbf{x}^{(n)})} = \frac{\pi_m}{\pi_{m'}} \times B_{m,m'}(\mathbf{x}^{(n)}), \quad m \neq m' = 1, \dots, M$$

where $B_{m,m'}(\mathbf{x}^{(n)})$ is the Bayes' factor for the model m against the model m' , that is,

$$B_{m,m'}(\mathbf{x}^{(n)}) = p(\mathbf{x}^{(n)}|m) / p(\mathbf{x}^{(n)}|m')$$

When using Bayes' factors, it is interesting to see that the posterior probability of the model m can be written under the following form:

$$p(m|\mathbf{x}^{(n)}) = \left\{ \sum_{m'=1}^M \frac{\pi_{m'}}{\pi_m} B_{m',m}(\mathbf{x}^{(n)}) \right\}^{-1}, \quad m = 1, \dots, M \quad [23]$$

Thus, the model selection will be based on the result [22] or on its equivalent version [23].

The model selection procedures usually tend to favor models of higher complexity, that is, those with the larger number of parameters. This is a consequence of the fact that the average amount of information provided by an experiment is non-negative (cf. Lindley, 1956; Kokolakis, 1981; Kokolakis, 1985). Although proper priors protect from overfitting, a problem which is very common within the frequentist approach, it might not be suitable to estimate a very large number of parameters using a rather small sample size. In such a case, a cross-validation based on the predictive distributions (cf. Draper, 1995), or the, rather conservative, Bayesian information criterion (BIC), due to Schwarz (1978), might be applied. The latter penalizes the model for the number of parameters it has. Specifically, the model to be chosen is that which maximizes the quantity

$$\text{BIC} = \log \max L(\theta_m, \mathbf{x}^{(n)}) - \frac{1}{2} k_m \log k_m$$

where k_m is the number of parameters within model m , that is, the dimension of θ_m .

Random Hyperparameters and Hierarchical Structures

Suppose that, according to our present state of knowledge K , the hyperparameter α , say, in the prior distribution of θ , is also a random quantity with its own prior distribution. Let \mathcal{A} be the set from which the hyperparameter α takes values. Then, we have the following results:

$$p(\mathbf{x}^{(n)}) = \int_{\mathcal{A}} p(\mathbf{x}^{(n)}|\boldsymbol{\alpha})p(\boldsymbol{\alpha})d\boldsymbol{\alpha}$$

with

$$p(\mathbf{x}^{(n)}|\boldsymbol{\alpha}) = \int_{\Theta} p(\mathbf{x}^{(n)}, \boldsymbol{\theta}|\boldsymbol{\alpha})d\boldsymbol{\theta} = \int_{\Theta} p(\mathbf{x}^{(n)}|\boldsymbol{\alpha}, \boldsymbol{\theta})p(\boldsymbol{\theta}|\boldsymbol{\alpha})d\boldsymbol{\theta} \quad [24]$$

the, conditional on $\boldsymbol{\alpha}$, predictive distribution of $\mathbf{x}^{(n)}$. The required posteriors are then given by

$$p(\boldsymbol{\alpha}|\mathbf{x}^{(n)}) \propto p(\boldsymbol{\alpha})p(\mathbf{x}^{(n)}|\boldsymbol{\alpha}) = p(\boldsymbol{\alpha}) \int_{\Theta} p(\mathbf{x}^{(n)}|\boldsymbol{\alpha}, \boldsymbol{\theta})p(\boldsymbol{\theta}|\boldsymbol{\alpha})d\boldsymbol{\theta} \quad [25]$$

and

$$p(\boldsymbol{\theta}|\boldsymbol{\alpha}, \mathbf{x}^{(n)}) \propto p(\boldsymbol{\theta}|\boldsymbol{\alpha})p(\mathbf{x}^{(n)}|\boldsymbol{\theta}, \boldsymbol{\alpha}) \quad [26]$$

Suppose now that the dataset $\mathbf{x}^{(n)}$ consists of k subsets, namely, $\mathbf{x}^{(n_i)} = \{\mathbf{x}_{ij}, j = 1, \dots, n_i\} (i = 1, \dots, k)$, coming from k populations, each one with its own parameter vector $\boldsymbol{\theta}_i$, a sub-vector of the collective parameter vector $\boldsymbol{\theta}$ above. We have, therefore, $\mathbf{x}^{(n)} = (\mathbf{x}^{(n_1)}, \dots, \mathbf{x}^{(n_k)})$ with $n = \sum_{i=1}^k n_i$. We may think of $\mathbf{x}^{(n_i)} (i = 1, \dots, k)$ as random samples of the same product that come from k production lines.

Now, consider the following hierarchical structure. The random samples $\mathbf{x}^{(n_i)} (i = 1, \dots, k)$, conditional on $\boldsymbol{\theta}_i i = 1, \dots, k$, respectively, are independent, and the parameters $\boldsymbol{\theta}_i i = 1, \dots, k$, conditional on the hyperparameter $\boldsymbol{\alpha}$, are independent and identically distributed according to $p(\cdot|\boldsymbol{\alpha})$. In other words, the random samples $\mathbf{x}^{(n_i)} (i = 1, \dots, k)$ are conditionally independent and the parameters $\boldsymbol{\theta}_i (i = 1, \dots, k)$, are exchangeable. Then, in place of [24]–[26] above, we have

$$p(\mathbf{x}^{(n)}|\boldsymbol{\alpha}) = \prod_{i=1}^k \left\{ \int_{\Theta} p(\mathbf{x}^{(n_i)}|\boldsymbol{\alpha}, \boldsymbol{\theta}_i)p(\boldsymbol{\theta}_i|\boldsymbol{\alpha})d\boldsymbol{\theta}_i \right\} \quad [27]$$

$$p(\boldsymbol{\alpha}|\mathbf{x}^{(n)}) \propto p(\boldsymbol{\alpha}) \prod_{i=1}^k \left\{ \int_{\Theta} p(\mathbf{x}^{(n_i)}|\boldsymbol{\alpha}, \boldsymbol{\theta}_i)p(\boldsymbol{\theta}_i|\boldsymbol{\alpha})d\boldsymbol{\theta}_i \right\} \quad [28]$$

$$p(\boldsymbol{\theta}|\boldsymbol{\alpha}, \mathbf{x}^{(n)}) \propto \prod_{i=1}^k p(\boldsymbol{\theta}_i|\boldsymbol{\alpha}, \mathbf{x}^{(n_i)})p(\mathbf{x}^{(n_i)}|\boldsymbol{\alpha}, \boldsymbol{\theta}_i) \quad [29]$$

The above hierarchical structure was introduced by Lindley and Smith (1972) in their seminal work on the Bayesian linear models. For a rather extensive range of applications of hierarchical structures in linear and generalized linear models, see Gelman *et al.* (2003) and Press (2003).

Glossary

Bias – Deviation between the true population value and the mean of a sample estimate (average over all possible samples).

Central limit theorem – It is the mathematical phenomenon which states that, as sample size tends to infinity, the sample mean follows normal curve (bell-shaped curve, also known as Gaussian curve) in limit.

Confidence interval – A sample data-based range such that a given population parameter lies within the range with a specified high probability (called confidence level).

Probability distribution – It describes a chance pattern according to which a random variable takes values.

Random variable – A statistical terminology used to describe a measurement or count which depends on chance.

Regression model – A statistical model used to describe the relationship of a variable of interest (called response variable) and a set of variables (called covariates) which are supposed to influence the response variable.

Sample estimator – A mathematical function of sample data used for approximating a population parameter (characteristic).

Standard error – The deviation between a true parameter value and its sample estimate is squared and averaged over all possible samples. Its square root is called standard error.

Time series – A sequence of measurements, taken at successive time points or intervals.

summarize a sample-based study and generalize the finding to the parent population in a scientific manner. A technical term for a sample summary number is (sample) statistic. Some basic sample statistics are sample mean, sample median, sample standard deviation, etc. Of course, a summary statistic like the sample mean will fluctuate from sample to sample and a statistician would like to know the magnitude of these fluctuations around the corresponding population parameter in an overall sense. This is then used in assessing margin of errors. The entire picture of all possible values of a sample statistics presented in the form of a probability distribution is called a sampling distribution. There is a plenty of theoretical knowledge of sampling distributions, which can be found in any text books of mathematical statistics. A general intuitive method applicable to just about any kind of sample statistic that keeps the user away from the technical tedium has got its own special appeal. Bootstrap is such a method.

To understand bootstrap, suppose it were possible to draw repeated samples (of the same size) from the population of interest, a large number of times. Then, one would get a fairly good idea about the sampling distribution of a particular statistic from the collection of its values arising from these repeated samples. But, that does not make sense as it would be too expensive and defeat the purpose of a sample study. The purpose of a sample study is to gather information cheaply in a timely fashion. The idea behind bootstrap is to use the data of a sample study at hand as a surrogate population, for the purpose of approximating the sampling distribution of a statistic; that is, to resample (with replacement) from the sample data at hand and create a large number of phantom samples known as bootstrap samples. The sample summary is then computed on each of the bootstrap samples (usually a few thousand). A histogram of the set of these computed values is referred to as the bootstrap distribution of the statistic.

In bootstrap's most elementary application, one produces a large number of copies of a sample statistic, computed from these phantom bootstrap samples. Then, a small percentage, say $100(\alpha/2)\%$ (usually $\alpha = 0.05$, is trimmed off from the lower as well as from the upper end of these numbers. The range of remaining $100(1-\alpha)\%$ values is declared as the confidence limits of the corresponding unknown population summary number of interest, with level of confidence $100(1-\alpha)\%$. The above method is referred to as bootstrap percentile method. We shall return to it later in the article.

Introduction and the Idea

Efron (1979) introduced the bootstrap method. It spread like brush fire in statistical sciences within a couple of decades. Now if one conducts a Google search for the above title, an astounding 1.86 million records will be mentioned; scanning through even a fraction of these records is a daunting task. We attempt first to explain the idea behind the method and the purpose of it at a rather rudimentary level. The primary task of a statistician is to

The Theoretical Support

Let us develop some mathematical notations for convenience. Suppose a population parameter θ is the target of a study; say, for example, θ is the household median income of a chosen community. A random sample of size n yields the data (X_1, X_2, \dots, X_n) . Suppose the corresponding sample statistic computed from this data set is $\hat{\theta}$ (sample median in the case of the example). For most sample statistics, the sampling distribution of $\hat{\theta}$ for large n ($n \geq 30$ is generally accepted as large sample size) is bell shaped with center θ and standard deviation (a/\sqrt{n}) , where the positive number a depends on the population and the type of statistic $\hat{\theta}$. This phenomenon is the celebrated central limit theorem (CLT). Often, there are serious technical complexities in approximating the required standard deviation from the data. Such is the case when $\hat{\theta}$ is sample median or sample correlation. Then bootstrap offers a bypass. Let $\hat{\theta}_B$ stand for a random quantity which represents the same statistic computed on a bootstrap sample drawn out of (X_1, X_2, \dots, X_n) . What can we say about the sampling distribution of $\hat{\theta}_B$ (w.r.t. all possible bootstrap samples), while the original sample (X_1, X_2, \dots, X_n) is held fixed? The first two articles dealing with the theory of bootstrap – Bickel and Freedman (1981) and Singh (1981) – provided large sample answers for most of the commonly used statistics. In limit, as $(n \rightarrow \infty)$, the sampling distribution of $\hat{\theta}_B$ is also bell shaped with $\hat{\theta}$ as the center and the same standard deviation (a/\sqrt{n}) . Thus, bootstrap distribution of $\hat{\theta}_B - \hat{\theta}$ approximates (fairly well) the sampling distribution of $\hat{\theta} - \theta$. Note that, as we go from one bootstrap sample to another, only $\hat{\theta}_B$ in the expression $\hat{\theta}_B - \hat{\theta}$ changes as $\hat{\theta}$ is computed on the original data (X_1, X_2, \dots, X_n) . This is the bootstrap CLT. For a proof of bootstrap CLT for the mean, reader is referred to Singh (1981).

Furthermore, it has been found that if the limiting sampling distribution of a statistical function does not involve population unknowns, bootstrap distribution offers a better approximation to the sampling distribution than the CLT. Such is the case when the statistical function is of the form $(\hat{\theta}_B - \hat{\theta})/\text{SE}$ where SE stands for true or sample estimate of the standard error of $\hat{\theta}$, in which case the limiting sampling distribution is usually standard normal. This phenomenon is referred to as the second-order correction by bootstrap. A caution is warranted in designing bootstrap, for second-order correction. For illustration, let $\theta = \mu$, the population mean, and $\hat{\theta} = \bar{X}$, the sample mean; σ = population standard deviation; s = sample standard deviation computed from original data; and s_B is the sample standard deviation computed on a bootstrap sample. Then, the sampling distribution of $(\bar{X} - \mu)/\text{SE}$, with $\text{SE} = \sigma/\sqrt{n}$, will be approximated by the bootstrap distribution of $(\bar{X}_B - \bar{X})/\text{SE}$, with \bar{X}_B = bootstrap sample mean and $\text{SE} = s/\sqrt{n}$. Similarly, the sampling distribution of $(\bar{X} - \mu)/\text{SE}$, with $\text{SE} = s/\sqrt{n}$,

will be approximated by the bootstrap distribution of $(\bar{X}_B - \bar{X})/\text{SE}_B$, with $\text{SE} = s_B/\sqrt{n}$. The earliest results on second-order correction were reported in Singh (1981) and Babu and Singh (1983). In the subsequent years, a flood of large sample results on bootstrap with substantially higher depth, followed. A name among the researchers in this area that stands out is Peter Hall of Australian National University.

Primary Applications of Bootstrap

Approximating Standard Error of a Sample Estimate

Let us suppose, information is sought about a population parameter θ . Suppose $\hat{\theta}$ is a sample estimator of θ based on a random sample of size n , that is, $\hat{\theta}$ is a function of the data (X_1, X_2, \dots, X_n) . In order to estimate standard error of $\hat{\theta}$, as the sample varies over the class of all possible samples, one has the following simple bootstrap approach.

Compute $(\theta_1^*, \theta_2^*, \dots, \theta_N^*)$, using the same computing formula as the one used for $\hat{\theta}$, but now base it on N different bootstrap samples (each of size n). A crude recommendation for the size N could be $N = n^2$ (in our judgment), unless n^2 is too large. In that case, it could be reduced to an acceptable size, say $n \log_e n$. One defines

$$\text{SE}_B(\hat{\theta}) = [(1/N) \sum_{i=1}^N (\theta_i^* - \hat{\theta})^2]^{1/2}$$

following the philosophy of bootstrap: replace the population by the empirical population.

An older resampling technique used for this purpose is Jackknife, though bootstrap is more widely applicable. The famous example where Jackknife fails while bootstrap is still useful is that of $\hat{\theta}$ = the sample median.

Bias Correction by Bootstrap

The mean of sampling distribution of $\hat{\theta}$ often differs from θ , usually by an amount $= c/n$ for large n . In statistical language, one writes

$$\text{Bias}(\hat{\theta}) = E(\hat{\theta}) - \theta \approx O(1/n)$$

A bootstrap based approximation to this bias is

$$\frac{1}{N} \sum_{i=1}^N \theta_i^* - \hat{\theta} = \text{Bias}_B(\hat{\theta}) \text{ (say)}$$

where θ_i^* are bootstrap copies of $\hat{\theta}$, as defined in the earlier subsection. Clearly, this construction is also based on the standard bootstrap thinking: replace the population by the empirical population of the sample. The bootstrap bias-corrected estimator is $\hat{\theta}_c = \hat{\theta} - \text{Bias}_B(\hat{\theta})$. It needs to be pointed out that the older resampling technique called Jackknife is more popular with statisticians for the purpose of bias estimation.

Bootstrap Confidence Intervals

Confidence intervals for a given population parameter θ are sample-based range $[\hat{\theta}_1, \hat{\theta}_2]$ given out for the unknown number θ . The range possesses the property that θ would lie within its bounds with a high (specified) probability. The latter is referred to as confidence level. Of course, this probability is with respect to all possible samples, each sample giving rise to a confidence interval which thus depends on the chance mechanism involved in drawing the samples. The two mostly used levels of confidence are 95% and 99%. We limit ourselves to the level 95% for our discussion here. Traditional confidence intervals rely on the knowledge of sampling distribution of $\hat{\theta}$, exact or asymptotic as $n \rightarrow \infty$. Here are some standard brands of confidence intervals constructed using bootstrap.

Bootstrap percentile method

This method was mentioned in the introduction itself, because of its popularity which is primarily due to its simplicity and natural appeal. Suppose one settles for 1000 bootstrap replications of $\hat{\theta}$, denoted by $(\theta_1^*, \theta_2^*, \dots, \theta_{1000}^*)$. After ranking from bottom to top, let us denote these bootstrap values as $(\theta_{(1)}^*, \theta_{(2)}^*, \dots, \theta_{(1000)}^*)$. Then the bootstrap percentile confidence interval at 95% level of confidence would be $[\theta_{(25)}^*, \theta_{(975)}^*]$. Turning to the theoretical aspects of this method, it should be pointed out that the method requires the symmetry of the sampling distribution of $\hat{\theta}$ around θ . The reason is that the method approximates the sampling distribution of $\hat{\theta} - \theta$ by the bootstrap distribution of $\hat{\theta} - \hat{\theta}_B$, which is contrary to the bootstrap thinking that the sampling distribution of $\hat{\theta} - \theta$ could be approximated by the bootstrap distribution of $\hat{\theta}_B - \hat{\theta}$. Interested readers are referred to Hall (1988).

Centered bootstrap percentile method

Suppose the sampling distribution of $\hat{\theta} - \theta$ is approximated by the bootstrap distribution of $\hat{\theta}_B - \hat{\theta}$, which is what the bootstrap prescribes. Denote 100 ϵ -th percentile of $\hat{\theta}_B$ (in bootstrap replications) by B_ϵ . Then, the statement that $\hat{\theta} - \theta$ lies within the range $B_{0.025} - \hat{\theta}, B_{0.975} - \hat{\theta}$ would carry a probability ≈ 0.95 . But, this statement easily translates to the statement that θ lies within the range $(2\hat{\theta} - B_{0.975}, 2\hat{\theta} - B_{0.025})$. The latter range is what is known as centered bootstrap percentile confidence interval (at coverage level 95%). In terms of 1000 bootstrap replications $B_{0.025} = \theta_{(25)}^*$ and $B_{0.975} = \theta_{(975)}^*$.

Bootstrap- t methods

As it was mentioned in section ‘The theoretical support’, bootstrapping a statistical function of the form $T = (\hat{\theta} - \theta)/SE$, where SE is a sample estimate of the standard error of $\hat{\theta}$, brings extra accuracy. This additional accuracy is due to so-called one-term Edgeworth correction by the bootstrap. The reader could find essential details in Hall (1992b). The basic example of T is the standard

t -statistics (from which the name bootstrap- t is derived): $t = (\bar{X} - \mu)/s/\sqrt{n}$, which is a special case with $\theta = \mu$ (the population mean), $\hat{\theta} = \bar{X}$ (the sample mean), and s standing for the sample standard deviation. The bootstrap counterpart of such a function T is $T_B = (\hat{\theta}_B - \theta)/SE_B$ where SE_B is exactly like SE but computed on a bootstrap sample. Denote the 100 ϵ -th bootstrap percentile of T_B by b_ϵ , and consider the statement: T lies within $[b_{0.025}, b_{0.975}]$. After the substitution $T = (\hat{\theta} - \theta)/SE$, the above statement translates to ‘ θ lies within $(\hat{\theta} - SE b_{0.975}, \hat{\theta} - SE b_{0.025})$ ’. This range for θ is called bootstrap- t -based confidence interval for θ at coverage level 95%. Such an interval is known to achieve higher accuracy than the earlier method, which is referred to as second-order accuracy in technical literature.

We conclude the section with a remark that B. Efron proposed correction to the rudimentary percentile method to bring in extra accuracy. These corrections are known as Efron’s ‘bias-correction’ and ‘accelerated bias-correction’. The details could be found in Efron and Tibshirani (1993). The bootstrap- t automatically takes care of such corrections, although the bootstrapper needs to look for a formula for SE which is avoided in the percentile method.

Some Real Data Example

Example 1 (Skewed Univariate Data). In the first example, the data are taken from Hollander and Wolfe (1999: 63), which represent the effect of illumination (difference between counts with and without illumination) on the rate of beak-clapping among chick-embryos. The boxplot suggests lack of normality of the population. We have carried out bootstrap analysis on the median and the mean. A noteworthy finding is the lack of symmetry of bootstrap- t histogram, which differs from limiting normal curve. The 95% level confidence intervals coming from our analysis for both mean and the median (centered bootstrap percentile method) cover the range [10, 30], roughly speaking. This range represents overall difference (increase) in the beak-clapping counts per minute due to illumination.

Example 2 (Bivariate Data). In this example, the data are from Collins *et al.* (1999), which assess body fat in collegiate football players (Devore, 2003: 553). We study correlation between the BOD and HW measurements; see the data at the end of this section. Here, BOD is BOD POD, a whole body air-displacement plethysmograph, and HW refers to hydrostatic weighing. The sample size is modest, but reasonable for bootstrap methods. As bivariate data consist of n pairs of data, say (X_i, Y_i) , for $i = 1, \dots, n$, one draws a pair of data randomly at a time in the bootstrap resampling. For instance, the first draw could be (X_7, Y_7) followed by (X_3, Y_3) , etc. The box plots of original data in **Figure 1(a)** suggest lack of normality of the underlying populations.

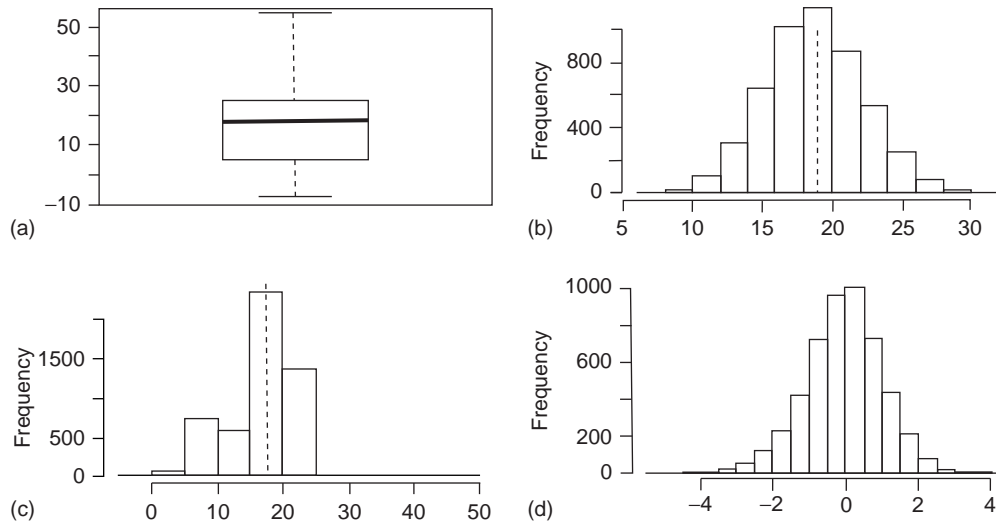

Figure 1 Boxplot of the measurement is presented in (a). Bootstrap distributions of the sample mean, sample median and t^* statistic are plotted in (b)–(d), respectively. The dotted lines in (b) and (c) correspond respectively to the sample mean and sample median. Based the bootstrap distributions, the 95% confidence interval for the population median by the bootstrap percentile method is (4.7000, 24.7000), by the centered bootstrap percentile is (10.5000, 30.5000). The 95% confidence interval for the population mean by the percentile bootstrap method is (10.0960, 28.1200) and by the centered bootstrap method is (9.4880, 27.51200). The bootstrap- t 95% CI for the population mean is (12.9413, 30.8147). Note that the bootstrap- t on the mean shows skewed histogram of the t -distribution.

The histogram for correlations computed on bootstrap bivariate data is plotted in **Figure 2(c)** which is asymmetric (skewed to the left). For this reason, the centered bootstrap percentile confidence interval appears more appropriate. According to our bootstrap analysis, the two measurements have at least a correlation of 0.78 in the population.

Data for Example 1:

-8.5 -4.6 -1.8 -0.8 1.9 3.9 4.7 7.1 7.5 8.5 14.8 16.7 17.6 19.7
20.6 21.9 23.8 24.7 24.7 25.0 40.7 46.9 48.3 52.8 54.0

Data for Example 2:

BOD

2.5 4.0 4.1 6.2 7.1 7.0 8.3 9.2 9.3 12.0 12.2 12.6 14.2 14.4 15.1
15.2 16.3 17.1 17.9 17.9

HW

8.0 6.2 9.2 6.4 8.6 12.2 7.2 12.0 14.9 12.1 15.3 14.8 14.3 16.3
17.9 19.5 17.5 14.3 18.3 16.2

Engineering: A Fitting Bootstrap

A sizable amount of journal literature on the topic is directed toward proposal and study of bootstrap schemes which will produce decent results in various statistical situations. The setup that has been the basis of forgoing discussion is basic and there are many types of departures from it. How to bootstrap in case of two-stage sampling or a stratified sampling? Natural schemes are not hard to think of. Bootstrapping in the case of data with regression models has attracted a lot of attention. There are two schemes which stand out: in one of which the covariate(s) and the

response variable are resampled together (called paired bootstrap), and the other one bootstraps the residuals (=response – fitted model value) and then reconstructs the bootstrap regression data by plugging in the estimated regression parameters (called residual bootstrap). Paired bootstrap remains valid – in the sense of correct outcome in the limit as $n \rightarrow \infty$, even if the error variances in the model are unequal; a property which the residual bootstrap lacks. The shortcoming is compensated by the fact that the latter scheme brings additional accuracy in the estimation of standard error. This is the classic tug of war between efficiency and robustness in statistics (see Liu and Singh, 1992a).

A lot harder to bootstrap are the time series data. Needless to say, time series analysis is of critical importance in several disciplines, especially in econometrics. The sources of difficulty are twofold: (1) Time series data possess serial dependence, that is, X_{T+1} has dependence on X_T , X_{T-1} , etc; (2) the statistical population changes with time, and that is known as nonstationarity. It was noted very early on (see Singh (1981) for m -dependent data) that the classical bootstrap cannot handle dependent data. A fair amount of research has been dedicated to modifying the bootstrap so that it could automatically bring in the dependence structure of the original sampling into bootstrap samples. The scheme of moving-block bootstrap has become quite well known (invented in Kunch (1989) and Liu and Singh (1992). Potitis and Romano are well-known authors on the topic, whose contributions have led to significant advancements on the topic of resampling, in general. In a moving block

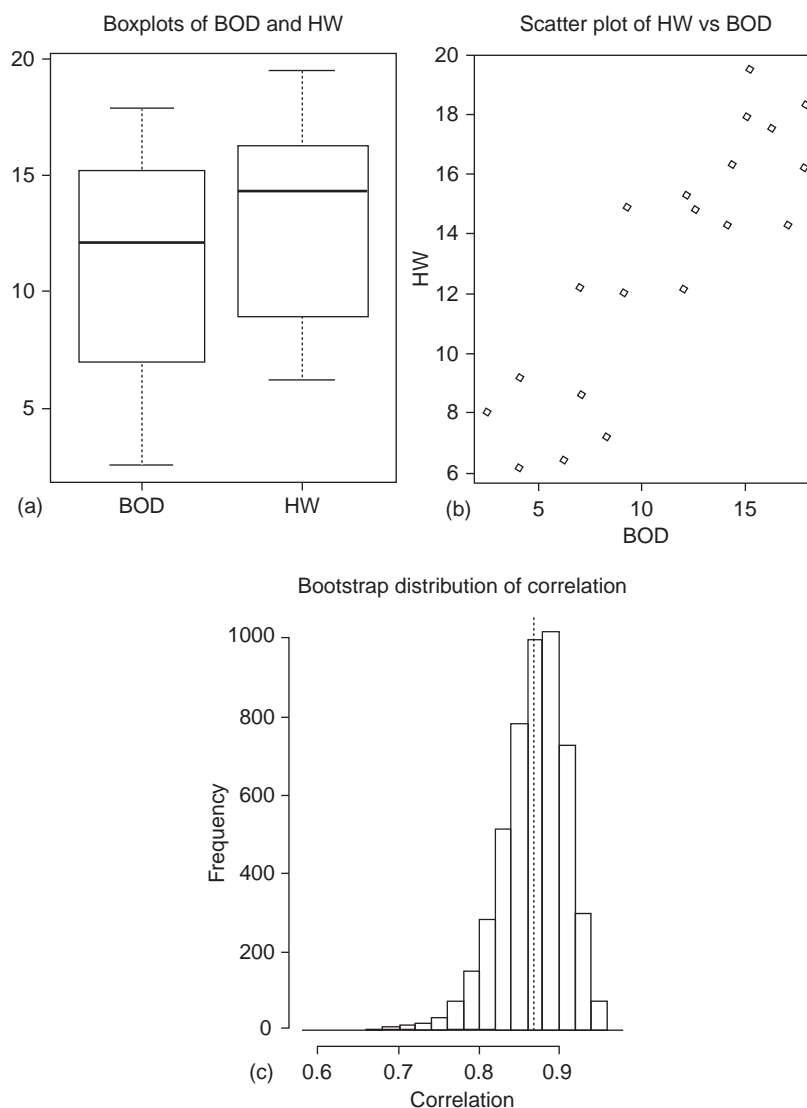

Figure 2 Boxplots of BOD and HW in (a) suggest somewhat non-normal data. Scatter plot in (b) indicates they are highly correlated. Bootstrap inference on the correlation between BOD and HW is presented in (c), which shows the bootstrap distribution (in histogram) of correlation. In particular, sample correlation of BOD and HW is 0.8679 which corresponds to the dotted vertical line in (c). The SE of the correlation is 0.0412 with an estimated bias of 0.0003. The 95% confidence interval of the correlation by the bootstrap percentile method is (0.7222, 0.9490) and the 95% confidence interval by the centered bootstrap percentile method is (0.7868, 1.0136).

bootstrap scheme, one draws a block of data at a time, instead of one of the X_i 's at a time, in order to preserve the underlying serial dependence structure that is present in the sample. There is plenty of ongoing research in the area of bootstrap methodology on econometric data.

The Great m out of n Bootstrap with $(m/n \rightarrow 0)$

There are various types of conditions under which the straightforward bootstrap becomes inconsistent, meaning that the bootstrap estimate of sampling distribution

and the true sampling distribution do not approach to the same limit, as the sample size n tends to ∞ . That means, for large samples, one is bound to end up with an inaccurate statistical inference. The examples include, just to name a few, bootstrapping sample minimum or sample maximum which estimate endpoint of a population distribution (Bickel and Freedman, 1981), the case of sample mean when the population variance is ∞ (Athreya, 1986) and bootstrapping sample eigenvalues when population eigenvalues have multiplicity (Eaton and Tyler, 1991), the case of sample median when the population density is discontinuous at the population median (Huang *et al.*, 1996). Luckily, a general remedy

exists and that is to keep the bootstrap sample size m much lower than the original size. Mathematically speaking, one requires $m \rightarrow \infty$ and $m/n \rightarrow 0$, as $n \rightarrow \infty$. In theory it fixes the problem; however for users, it is somewhat troublesome. How to choose m ? An obvious suggestion would be settle for a fraction of n , say 20% or so. It should be pointed out that in good situations, where the regular bootstrap is fine, such an m is not advisable as it will result in loss of efficiency (see Bickel (2003), for a recent survey on the topic).

Introduction

In statistics and data analysis, we are often interested in the relationship and interdependence between two or more variables. The simplest known measure in this respect is the simple correlation coefficient ρ between two variables, usually measured by the product moment estimator, which measures the linear relationship between two variables. Other measures such as the partial correlation coefficient provide refinements to this idea when the correlation between two variables needs to be adjusted for the presence of other variables.

However, sometimes, we are interested in the correlation between one variable X and another set of variables Y , or, more generally, between two different sets X and Y , each having more than one variable. Canonical correlation analysis quantifies the association between two sets of such variables. In the particular case when one of the two groups – say the first group – has only one variable, the linear dependence between this variable X and the variables of the other group Y is quantified through the multiple correlation, the maximum correlation between X and a linear combination of the Y variables. Canonical correlation, which may be called the multiple, multiple correlation, is a further generalization of this idea. It is a dimension reduction technique which attempts to describe the high-dimensional relationship between two groups of variables in terms of a small number of canonical variable pairs. The procedure was initially developed by Hotelling (1935, 1936) in the 1930s.

Canonical correlation analysis focuses on the correlation between a linear combination of the variables in one set and another linear combination of the variables in the other set. The idea is to first determine U_1 and V_1 , linear combinations of the X and Y variables, respectively, such that the correlation between U_1 and V_1 is the highest possible among all such linear combinations. Next, we determine a new pair of linear combinations, say U_2 and V_2 , which has the highest correlation subject to U_2 being uncorrelated with U_1 , and V_2 being uncorrelated with V_1 (the construction actually ensures that U_1 and V_2 are uncorrelated as well, as are U_2 and V_1). The process continues until a subsequent pair of linear combinations no longer produces a significant correlation. The pairs of linear combinations are called the canonical variables, and their correlations are the canonical correlations.

In addition to describing the nature of the relationship between two latent variables, canonical correlation

analysis is useful in determining how many dimensions are needed to account for the relationship. If there are two groups of variables, one containing m variables and the other containing n variables, there could be $m \times n$ different correlations between the different variable pairs of the two sets. Canonical correlation analysis tries to describe this structure in terms of a fewer number of correlations and variable pairs; this number will be no larger than the minimum of m and n .

Canonical Correlations

Let X represent the first set of variables, and let Y denote the second set of variables. Assume that X is m dimensional, and let the dimension of Y be n . Without loss of generality, let $m \leq n$. Let $\text{Cov}(X)$, $\text{Cov}(Y)$ and $\text{Cov}(X, Y)$ be denoted by $\Sigma_{11}^{m \times m}$, $\Sigma_{22}^{n \times n}$, and $\Sigma_{12}^{m \times n}$, respectively, with the superscripts denoting the dimensions of the matrices. We will drop the superscripts when there is no scope for confusion. We will assume that the $(m+n) \times (m+n)$ dimensional square matrix

$$\Sigma = \begin{pmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{pmatrix}$$

is positive definite, where $\Sigma_{21} = \Sigma_{12}^T$. We will generalize the concept of multiple correlation and describe the correlation structure resulting from the elements of Σ in terms of appropriately chosen pairs of canonical variables.

We will consider linear combinations of the form

$$U_1 = a_1^T X \quad \text{and} \quad V_1 = b_1^T Y \quad [1]$$

where a_1 and b_1 are m and n dimensional coefficient vectors, respectively. From standard statistical theory, we have

$$\text{Var}(U_1) = a_1^T \Sigma_{11} a_1, \quad \text{Var}(V_1) = b_1^T \Sigma_{22} b_1 \quad \text{and}$$

$$\text{Cov}(U_1, V_1) = a_1^T \Sigma_{12} b_1$$

Thus, the correlation between the variables U_1 and V_1 is given by

$$\text{Corr}(U_1, V_1) = \frac{a_1^T \Sigma_{12} b_1}{\sqrt{a_1^T \Sigma_{11} a_1} \sqrt{b_1^T \Sigma_{22} b_1}} \quad [2]$$

Our aim is to choose a_1 and b_1 to maximize the above correlation. The quantity

$$\max_{a_1, b_1} \text{Corr}(U_1, V_1) \quad [3]$$

obtained as a result of the above maximization will be referred to as the first canonical correlation between the

sets X and Y and the corresponding variable pair will be denoted as the first canonical variable pair. Later we will continue the description in terms of the second, third, and subsequent canonical variable pairs.

The development of the canonical correlations will require a few mathematical tools involving eigenvalues and eigenvectors of nonnegative definite matrices, which we state in the following (without proofs). The proofs are available in most standard texts of linear algebra or applied multivariate analysis. Johnson and Wichern (2006), for example, is a typical reference.

Lemma 1: Suppose A is a $p \times p$ nonnegative definite matrix having eigenvalues $\lambda_1 \geq \dots \geq \lambda_j \geq \dots \geq \lambda_p$, with corresponding orthonormal eigenvectors $e_1, \dots, e_j, \dots, e_p$.

- (i) Let s be any p dimensional vector. We are interested in the maximum value of the normalized quadratic form in A over all non-null vectors s . This maximum is given by

$$\max_{s \neq 0} \frac{s^T A s}{s^T s} = \lambda_1 \quad [4]$$

where λ_1 is the largest eigenvalue of A . The maximum is attained when $s = e_1$.

- (ii) Among all nonnull p dimensional vectors s which are orthogonal to e_1, \dots, e_{j-1} , $j = 2, \dots, p$, the same maximization problem leads to

$$\max_{s \perp e_1, \dots, e_{j-1}} \frac{s^T A s}{s^T s} = \lambda_j \quad [5]$$

and this maximum is attained at $s = e_j$.

Define the matrices M and N as

$$\begin{aligned} M &= \Sigma_{11}^{-1/2} \Sigma_{12} \Sigma_{22}^{-1} \Sigma_{21} \Sigma_{11}^{-1/2} \quad \text{and} \\ N &= \Sigma_{22}^{-1/2} \Sigma_{21} \Sigma_{11}^{-1} \Sigma_{12} \Sigma_{22}^{-1/2} \end{aligned} \quad [6]$$

where $\Sigma_{11}^{-1/2}$ and $\Sigma_{22}^{-1/2}$ are positive definite square roots of Σ_{11}^{-1} and Σ_{22}^{-1} , respectively. Notice that the matrix M can be written in the form BB^T where $B = B_{m \times n} = \Sigma_{11}^{-1/2} \Sigma_{12} \Sigma_{22}^{-1/2}$, and hence M is non-negative definite. Similarly, N can be written as $B^T B$, and hence N is non-negative definite as well. This representation also shows that the set of nonzero eigenvalues of M and N are the same (this is a consequence of the eigenvalues of CD and DC being the same, wherever the multiplication of the matrices C and D , and D and C , are defined); in particular if ρ_1 is the largest eigenvalue of M , it is also the largest eigenvalue of N . Also if e is a normalized eigenvector of M corresponding to some nonzero eigenvalue ρ , then $B^T e$ is an eigenvector of N associated with the eigenvalue ρ ; division by $\sqrt{\rho}$ reduces the length of this eigenvector to 1. Thus,

$$f = B^T e / \sqrt{\rho} \quad [7]$$

is a normalized eigenvector of N associated with the eigenvalue ρ .

With this background, we are now ready to state and prove the following theorems.

Theorem 1: The elements of the first canonical variable pair (U_1, V_1) are given by

$$U_1 = e_1^T \Sigma_{11}^{-1/2} X \quad \text{and} \quad V_1 = f_1^T \Sigma_{22}^{-1/2} Y$$

where e_1 and f_1 are the normalized eigenvectors associated with the largest eigenvalue ρ_1 of M and N , respectively. The value of the first canonical correlation is $\sqrt{\rho_1}$.

Proof: We consider linear combinations $U_1 = a_1^T X$ and $V_1 = b_1^T Y$ with the aim of maximizing $\text{Corr}(U_1, V_1)$ over a_1 and b_1 . Let $c_1 = \Sigma_{11}^{-1/2} a_1$ and $d_1 = \Sigma_{22}^{-1/2} b_1$. Using eqn [2], we can represent the correlation coefficient between U_1 and V_1 :

$$\begin{aligned} \text{Corr}(U_1, V_1) &= \frac{a_1^T \Sigma_{12} b_1}{\sqrt{a_1^T \Sigma_{11} a_1} \sqrt{b_1^T \Sigma_{22} b_1}} \\ &= \frac{c_1^T \Sigma_{11}^{-1/2} \Sigma_{12} \Sigma_{22}^{-1/2} d_1}{\sqrt{c_1^T c_1} \sqrt{d_1^T d_1}} \end{aligned} \quad [8]$$

By a simple application of the Cauchy-Schwarz theorem, we observe that the numerator on the right-hand side of the quantity in eqn [8] is bounded above by

$$\left(c_1^T \Sigma_{11}^{-1/2} \Sigma_{12} \Sigma_{22}^{-1/2} \Sigma_{21} \Sigma_{11}^{-1/2} c_1 \right)^{1/2} (d_1^T d_1)^{1/2}$$

and the substitution of this in eqn [8] gives

$$\begin{aligned} \text{Corr}(U_1, V_1) &\leq \frac{(c_1^T \Sigma_{11}^{-1/2} \Sigma_{12} \Sigma_{22}^{-1/2} \Sigma_{21} \Sigma_{11}^{-1/2} c_1)^{1/2}}{(c_1^T c_1)^{1/2}} \\ &= \frac{(c_1^T M c_1)^{1/2}}{(c_1^T c_1)^{1/2}} \leq \sqrt{\rho_1} \end{aligned} \quad [9]$$

The last inequality follows from eqn [4]. Thus, $\text{Corr}(U_1, V_1)$ is bounded by $\sqrt{\rho_1}$, where ρ_1 is the largest eigenvalue of M .

It remains to show that $\text{Corr}(U_1, V_1)$ attains this bound for the particular choices $a_1 = \Sigma_{11}^{-1/2} e_1$ and $b_1 = \Sigma_{22}^{-1/2} f_1$. Since e_1 and f_1 are normalized eigenvectors, direct substitution of the expressions in eqn [8] gives

$$\text{Corr}(U_1, V_1) = \frac{(e_1^T \Sigma_{11}^{-1/2} \Sigma_{12} \Sigma_{22}^{-1/2} f_1)}{\sqrt{(e_1^T e_1)} (f_1^T f_1)} = e_1^T B f_1 \quad [10]$$

An application of eqn (7) shows

$$\text{Corr}(U_1, V_1) = \frac{e_1^T B B^T e_1}{\sqrt{\rho_1}} = \frac{e_1^T M e_1}{\sqrt{\rho_1}} = \frac{\rho_1 e_1^T e_1}{\sqrt{\rho_1}} = \sqrt{\rho_1} \quad [11]$$

which establishes the desired result.

The last part of the proof can also be shown by checking that these particular choices of a_1 and b_1 lead to equalities in both the inequalities of eqn [9].

Notice that since we are maximizing a correlation which is a scale-independent measure, the value of the correlation would remain the same if the coefficient vectors a_1 and b_1 were multiplied by any scalar constants. The

particular choice given here ensures that the variance of the variables U_1 and V_1 are equal to unity. This is presented more formally later in Theorem 3.

Theorem 2: The j th pair of canonical variables (U_j, V_j) , $j = 2, \dots, m$, are given by

$$U_j = \mathbf{e}_j^T \Sigma_{11}^{-1/2} X \quad \text{and} \quad V_j = \mathbf{f}_j^T \Sigma_{22}^{-1/2} Y$$

where \mathbf{e}_j and \mathbf{f}_j are the orthonormal eigenvectors associated with the j th largest eigenvalue ρ_j of M and N . The j th canonical correlation is given by $\text{Corr}(U_j, V_j) = \sqrt{\rho_j}$.

Proof: We will determine linear combinations $U_2 = \mathbf{a}_2^T X$ and $V_2 = \mathbf{b}_2^T Y$ such that $\text{Corr}(U_2, V_2)$ is maximized subject to $\text{Cov}(U_1, U_2) = \text{Cov}(V_1, V_2) = 0$. By denoting $\mathbf{a}_2 = \Sigma_{11}^{-1/2} \mathbf{c}_2$ and $\mathbf{b}_2 = \Sigma_{22}^{-1/2} \mathbf{d}_2$, we get

$$\begin{aligned} \text{Cov}(U_1, U_2) &= \text{Cov}(\mathbf{e}_1^T \Sigma_{11}^{-1/2} X, \mathbf{c}_2^T \Sigma_{11}^{-1/2} X) \\ &= \mathbf{e}_1^T \Sigma_{11}^{-1/2} \Sigma_{11} \Sigma_{11}^{-1/2} \mathbf{c}_2 \end{aligned}$$

Thus, $\text{Cov}(U_1, U_2) = 0$ implies that \mathbf{c}_2 must belong to the orthogonal space of \mathbf{e}_1 . Similarly, \mathbf{d}_2 can be shown to belong to the orthogonal space of \mathbf{f}_1 .

Therefore, we will have to maximize

$$\text{Corr}(U_2, V_2) = \frac{\mathbf{c}_2^T \Sigma_{11}^{-1/2} \Sigma_{12} \Sigma_{22}^{-1/2} \mathbf{d}_2}{\sqrt{\mathbf{c}_2^T \mathbf{c}_2} \sqrt{\mathbf{d}_2^T \mathbf{d}_2}} \quad [12]$$

subject to the restrictions on \mathbf{c}_2 and \mathbf{d}_2 . As in Theorem 1, an application of the Cauchy–Schwarz inequality gives

$$\text{Corr}(U_2, V_2) \leq \frac{(\mathbf{c}_2^T M \mathbf{c}_2)^{1/2}}{(\mathbf{c}_2^T \mathbf{c}_2)^{1/2}} \leq \sqrt{\rho_2} \quad [13]$$

where the last inequality follows from Lemma 1 (ii). Direct substitution shows that equality is attained for $\mathbf{c}_2 = \Sigma_{11}^{-1/2} \mathbf{e}_2$ and $\mathbf{d}_2 = \Sigma_{22}^{-1/2} \mathbf{f}_2$.

The result for the successive canonical correlations can be proved in a similar fashion.

Theorem 3: The canonical variable pairs have the properties

$$\text{Var}(U_j) = \text{Var}(V_j) = 1, \quad j = 1, \dots, m \quad [14]$$

$$\text{Cov}(U_j, U_k) = \text{Corr}(U_j, U_k) = 0, \quad j \neq k \quad [15]$$

$$\text{Cov}(V_j, V_k) = \text{Corr}(V_j, V_k) = 0, \quad j \neq k \quad [16]$$

$$\text{Cov}(U_j, V_k) = \text{Corr}(U_j, V_k) = 0, \quad j \neq k \quad [17]$$

Proof: Property [14] is easily verifiable from the definition of the canonical variables, and properties [15] and [16] follow from the construction of the canonical correlation

pairs as outlined in Theorem 2. For property [17], note that

$$\begin{aligned} \text{Cov}(U_j, V_k) &= \mathbf{e}_j^T \Sigma_{11}^{-1/2} \Sigma_{12} \Sigma_{22}^{-1/2} \mathbf{f}_k \\ &= \mathbf{e}_j^T M \mathbf{e}_k / \sqrt{\rho_k} \\ &= 0 \end{aligned}$$

The last inequality follows from the fact that the vectors \mathbf{e}_j and \mathbf{e}_k are orthonormal eigenvectors of M . The previous equality follows from eqn [7].

In real situations where actual data are generated from the variables of interest, the theoretical quantities in the setup described in Theorems 1–3 are replaced by their sample analogs. Thus, for example, the population covariance matrix Σ will be replaced by the sample covariance matrix S .

Miscellaneous Issues

Canonical correlations are, in general, abstract quantities and one must be careful when interpreting them. At times, some meaningful interpretation can be attached to these by going to lower levels appropriately. By the nature of their construction, canonical correlations are always positive. For two scalar variables, the (single) canonical correlation between them is the absolute value of their ordinary correlation coefficient. The (single) canonical correlation between a scalar variable and a group of variables is – as referred to earlier – quantified by the multiple correlation coefficient. The multiple correlation coefficient is linked to the multiple regression setup and has clear interpretability; it is the correlation between a dependent variable and its best linear predictor.

In the case of two groups each having more than one variable, the j th canonical correlation may be viewed as the multiple correlation between U_j and Y (or the multiple correlation between V_j and X).

An Example with Real Data

In this section, we present a simple example to demonstrate the ideas presented in this article. The data, presented in Waugh (1957), are also available at

<http://lib.stat.cmu.edu/DASL/Datafiles/agecondat.html>

which contain information on the price and consumption per capita of beef and pork in the United States annually from 1925 to 1941 together with other variables relevant to an economic analysis of price and/or consumption of beef and pork over the period (Table 1). The variables that we included in our analysis are

X_1 = Price of beef (cents/lb)

X_2 = Price of pork (cents/lb)

Y_1 = Consumption of beef per capita (lbs)

Y_2 = Consumption of pork per capita (lbs)

The correlation matrix of $(X_1, X_2, Y_1, Y_2)^T$ is given by

$$\begin{pmatrix} 1 & 0.3268 & -0.7524 & -0.3462 \\ 0.3268 & 1 & 0.0834 & -0.7837 \\ -0.7524 & 0.0834 & 1 & -0.2915 \\ -0.3462 & -0.7837 & -0.2915 & 1 \end{pmatrix}$$

The scatter plots of all the pairs of (X, Y) variables are presented in **Figure 1**. As one would expect, X_1 and Y_1 are strongly (negatively) correlated, while X_2 and Y_2 also have a high negative correlation.

The canonical coefficients (a_1 and a_2) for the X variables are given along the columns of the following matrix

Table 1 Consumption and price of beef and pork over the years 1925–41

Year	X_1	X_2	Y_1	Y_2
1925	59.7	60.5	58.6	65.8
1926	59.7	63.3	59.4	63.3
1927	63.0	59.9	53.7	66.8
1928	71.0	56.3	48.1	69.9
1929	71.0	55.0	49.0	68.7
1930	74.2	59.6	48.2	66.1
1931	72.1	57.0	47.9	67.4
1932	79.0	49.5	46.0	69.7
1933	73.1	47.3	50.8	68.7
1934	70.2	56.6	55.2	62.2
1935	82.2	73.9	52.2	47.7
1936	68.4	64.4	57.3	54.4
1937	73.0	62.2	54.4	55.0
1938	70.2	59.9	53.6	57.4
1939	67.8	51.0	53.9	63.9
1940	63.4	41.5	54.2	72.4
1941	56.0	43.9	60.0	67.4

$$\begin{pmatrix} 0.1265 & 0.0859 \\ 0.0341 & -0.1265 \end{pmatrix}$$

and the canonical coefficients for the Y variables are, column-wise,

$$\begin{pmatrix} -0.2066 & -0.1303 \\ -0.1191 & 0.1028 \end{pmatrix}$$

The two canonical correlations for our variables are equal to 0.9728 and 0.7034. The scatter plot of the canonical variables is given in **Figure 2**. The strong linear nature of the relationship among the variables in the first canonical variable pair is clearly observed both from the magnitude of the first canonical correlation, as well as from the corresponding scatter plot. This relationship is much stronger than that among any of the pairs of the original variables. Even the second canonical correlation has a fairly strong linear dependence and the second canonical correlation has a reasonably high value. The scatter plots of the cross canonical variables are presented in **Figure 3** where we plot U_2 against U_1 , V_2 against V_1 , V_2 against U_1 , and V_1 against U_2 .

As expected, the scatter plots in **Figure 3** exhibit a completely random pattern, consistent with the zero correlation these pairs are expected to have. Numerically, the actual computed correlations are

$$\text{Corr}(U_1, U_2) = 9.7145 \times 10^{-17}$$

$$\text{Corr}(U_1, V_2) = 1.1102 \times 10^{-16}$$

$$\text{Corr}(V_1, V_2) = -3.8858 \times 10^{-16}$$

$$\text{Corr}(U_2, V_1) = -1.3878 \times 10^{-16}$$

which are practically equal to zero. On the whole, the canonical correlations give a neat description of the correlation structure of the two groups of variables in this example.

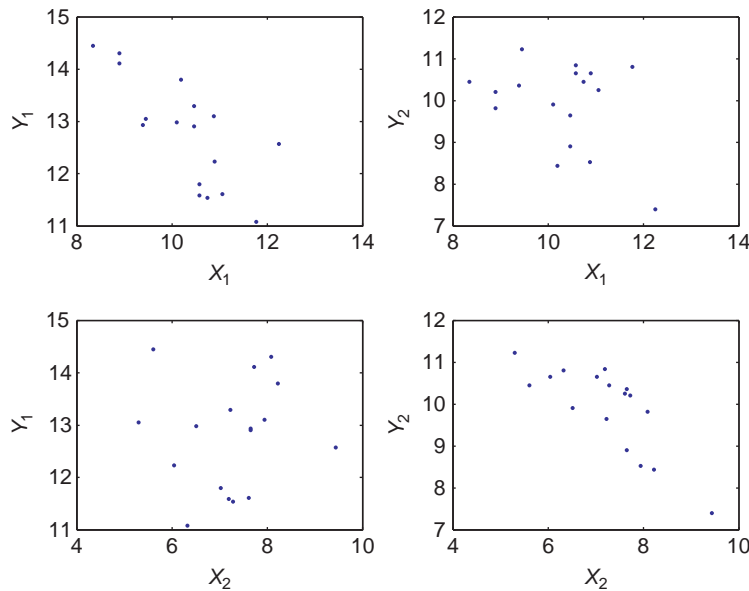

Figure 1 Scatter plots of the Y variables versus the X variables.

Uses of Canonical Correlations

In this section, we provide a very brief outline of the use of canonical correlations in a variety of different settings and some basic references for it for the benefit of the interested reader.

There are many standard textbooks in multivariate analysis which deal adequately with canonical correlations. Useful references, among others, include Anderson (2003) and Johnson and Wichern (2006).

Many useful web-based tutorials of canonical correlation are also available on the Internet (see, e.g., Borga (1999) and Garson (2008)).

Figure 2 Scatter plots of the canonical variable pairs.

As explained earlier, the interpretation of canonical correlations can be a tricky matter, and there is an expanded literature which deals with this issue. (See, for example, Alpert and Peterson (1972) who discuss possible difficulties of interpreting canonical correlations as measures of the magnitude of relationship between two sets of variables.)

The canonical correlation idea can be extended to define generalized canonical correlation analysis (GCCA) where the classical two set canonical correlation approach is extended to more than two sets. For more details, see Kettenring (1971).

Canonical correlation analysis, in its standard setting, studies the linear relationship between the canonical variables. This approach may be generalized to study the nonlinear relation between two sets of random variables (see Gifi (1990, Chapter 6) for a useful discussion of nonlinear canonical correlation analysis (NCCA)). The method of kernel canonical correlation analysis (KCCA) has also been found to be useful when the embedding of common features is nonlinear or the relation between features is not Gaussian (see, e.g., Akaho (2001)).

Multivariate normality is usually demanded for significance testing in canonical correlation analysis. Choice of an adequate sample size to ensure reasonable power has received some attention in the literature in this context (see Barcikowski and Stevens (1975) and Stevens (1986) for some discussion and recommendations on this issue).

Sometimes, the canonical coefficients are used to determine which original variable(s) a canonical correlation is primarily associated with. This is generally a reasonable approach but can lead to incorrect results when there is high multicollinearity in the data. More discussion

Figure 3 Scatter plots of the cross-canonical variables.

together with alternative recommendations can be found in Levine (1977).

Sometimes, some natural restrictions on the canonical correlations have to be taken into account when performing the analysis. Approaches to perform canonical correlation analysis under such restrictions have been discussed in Das and Sen (1994).

Categorical Data Analysis

S E Fienberg and B W Junker, Carnegie Mellon University, Pittsburgh, PA, USA

© 2010 Elsevier Ltd. All rights reserved.

Introduction

Categorical data are ubiquitous and essential in education research. Examples include explanatory variables, such as gender, ethnicity, type of instruction, etc., and response variables such as individual test item scores, total test scores, and achievement levels. Understanding dependence – and independence – relationships among such variables is an essential statistical task in education research. In this article, we survey four key tools for this task: log-linear models for contingency tables, the Cochran–Mantel–Haenszel (CMH) test, logistic regression, and latent variable models.

Contingency Tables

A contingency table consists of counts of units cross-classified according to the values of several categorical (nominal or ordinal) variables. **Table 1** contains counts cross-classified units according to two nominal variables, gender (male/female) and white (yes/no); and two ordinal variables, frequency of math drills (never, seldom, weekly, often, daily) and NAEP achievement level (below basic, basic, proficient, advanced).

Testing for Relationships Among Categorical Variables

What can we learn from **Table 1**? For example, do male students typically perform above, or below, female students? Summing the counts for male and female students separately we arrive at **Table 2**, to which we can apply the Pearson chi-squared test of statistical independence (e.g., Fienberg, 1980), finding $X^2 = 1.930$ on 3 degrees of freedom (df). There is no evidence to support the hypothesis of differential performance on the assessment by gender ($P(X^2 > 1.930) = 0.59$).

Log-linear models (Bishop *et al.*, 1975; Fienberg, 1980) can help extend analyses like this. For **Table 2**, write each count as n_{ij} , indexed by i for gender and j for achievement level, and write the log-linear model as

$$\log E(n_{ij}) = \log(p_{ij}n) = u + u_{1(i)} + u_{2(j)} + u_{12(ij)} \quad [1]$$

which has the same form as an ANOVA model for the factors u_1 (gender) and u_2 (achievement level). Here, $p_{ij} = P$

(gender = i achievement = j) and $n = \sum_i \sum_j n_{ij}$, with constraints such as

$$\sum_{i=1}^2 u_{1(i)} = \sum_{j=1}^4 u_{2(j)} = \sum_{i=1}^2 u_{12(ij)} = \sum_{j=1}^4 u_{12(ij)} = 0 \quad [2]$$

following Bishop *et al.* (1975). (Any single linear constraint for each subscript in a subscripted u -term, such as setting the first or last value equal to zero is equivalent for the purpose of these expectations.) The above chi-squared test is equivalent to testing whether the interaction terms $u_{12(ij)}$ are all zero in the log-linear model. Model [1] with the $u_{12(ij)}$ all zero is equivalent to statistical independence since, in that case, from eqn [1], $p_{ij}n = \exp(u) \cdot \exp(u_{1(i)}) \cdot \exp(u_{2(j)})$, and this can be used to express

$$p_{ij} = p_i \times p_j \quad [3]$$

Alternatively, the likelihood-ratio statistic comparing the log-additive model ($u_{12(ij)} \equiv 0$) to the saturated model in eqn [1] is $G^2 = 1.929$ on 3 df. The X^2 and G^2 statistics are usually close in value, differing mainly in the presence of small cell counts.

For a 2×2 table such as **Table 3**, another common measure of dependence is the odds ratio

$$\begin{aligned} OR &= \frac{\text{odds}(X_2 = 2 | X_1 = 2)}{\text{odds}(X_2 = 2 | X_1 = 1)} \\ &= \frac{P(X_2 = 2 | X_1 = 2) / (1 - P(X_2 = 2 | X_1 = 2))}{P(X_2 = 2 | X_1 = 1) / (1 - P(X_2 = 2 | X_1 = 1))} \\ &= \frac{p_{11}p_{22}}{p_{12}p_{21}} \end{aligned}$$

which can be estimated as

$$\overline{OR} = \frac{n_{11}n_{22}}{n_{12}n_{21}} \quad [4]$$

From eqns [1] and [2]

$$u_{12(11)} = \frac{1}{4} \log(OR) \quad [5]$$

Hence we can use the log-linear model in eqn [1] to estimate the odds ratio. (Had we used another type of constraint, for example, setting $u_{12(11)} = u_{12(11)} = u_{12(11)} = 0$, then $u_{12(22)} = \log(OR)$. In all cases, we have a scaled function of $\log(OR)$.) When $OR > 1$ ($u_{12(11)} > 0$), the variables in the table are positively associated; when $OR < 1$ ($u_{12(11)} < 0$), they are negatively associated. $OR = 1$ ($u_{12(11)} = 0$) corresponds to statistical independence, as can be seen by substituting [3] into [4].

Table 1 Number of eighth-grade students at each achievement level, cross-classified by gender, ethnicity (white/nonwhite), and frequency of mathematics drills in the classroom

Hierarchical Log-Linear Models

A shorthand notation helps in specifying interpretable log-linear models: the notation $[1][2]$ refers to the additive model $u + u_{1(i)} + u_{2(j)}$, the notation $[12]$ refers to the model with $u_{12(jk)}$ and all lower-order terms: $u + u_{1(i)} = u_{2(j)} = u_{12(ij)}$ as in eqn [1], and so forth.

These are called hierarchical log-linear models because, by convention, the inclusion of interaction terms like $[12]$ implies inclusion of all lower-order terms; this is known as the hierarchy principle. For example, for a four-way table like **Table 1**, the model $[134][234]$ includes the two three-way interaction terms $u_{134(ikl)}$ and $u_{234(jkl)}$, as well as all two-way interactions except for $u_{12(ij)}$ and all main effects, that is,

$$\log E(n_{ijkl}) = u + u_{1(i)} + u_{2(j)} + u_{3(k)} + u_{4(l)} + u_{13(ik)} + u_{14(il)} + u_{34(kl)} + u_{23(jk)} + u_{24(jl)} + u_{134(ikl)} + u_{234(jkl)}$$

Holding factors 3 and 4 at fixed levels k_0 and l_0 in this model, most terms in the model are constant and the only terms that vary with factors 1 and 2 are additive,

$$\log E(n_{ijk_0l_0}) = u + u_{3(k_0)} + u_{4(l_0)} + u_{34(k_0l_0)} + u_{1(i)} + u_{13(ik_0)} + u_{14(il_0)} + u_{134(ik_0l_0)}$$

indicating conditional independence of factors 1 and 2, given factors 3 and 4.

We use hierarchical log-linear models to assess dependence among multiple variables cross-classifying counts in a contingency table. Special cases of these models, the log-linear graphical and decomposable models, allow us to search large contingency tables efficiently for independence, conditional independence, and dependence relationships that are suggestive about the causal structure of the underlying data generating process.

When the model of statistical independence $[1][2][3][4]$

$$\log E(n_{ij}) = u + u_{1(i)} + u_{2(j)} + u_{3(k)} + u_{4(l)}$$

is applied to **Table 1**, the likelihood-ratio statistic is $G^2 = 549.18$ on 70 df, strongly suggesting that the four factors are not statistically independent. Further likelihood-ratio testing reveals that the two-way interactions

Figure 1 Achievement level percentages within gender, ethnicity, and math drill frequency, computed from **Table 1**.

(also known as first-order interactions) and some three-way interactions (also known as second-order interactions) should be included in the model. But the model [123][423] fits well, $G^2 = 12.75$ on 30 df, implying that gender (factor 1) is conditionally independent of achievement (factor 4) given ethnicity and drill frequency (factors 2 and 3).

Figure 1 shows the percentage of students at each achievement level in each row of **Table 1**. Evidently, the general achievement pattern is the same for males and females, confirming our log-linear analysis, although there are some differences in levels according to ethnicity that might warrant further exploration.

More troubling is that the percentage at the below basic achievement level increases with frequency of math drills, whereas percentages at the higher achievement levels all decrease as math drills become more frequent. A more detailed analysis would show that these trends are statistically significant, not explainable as chance variation alone. Since math drills precede the NAEP assessment, does this suggest that more math drills cause students to perform more poorly? Perhaps, a hidden third variable – students' prior mathematics achievement – influences both the NAEP test score and the decision to expose students to more or less frequent math drills. Thus, it is wise to keep the maxim "correlation (or association) does not mean causation" clearly in mind.

CMH Procedure

Simpson's Paradox and Association Reversal Phenomena

For **Table 1**, we hypothesized that the relationship between frequency of math drill and achievement level could be explained by an unobserved third variable, students' prior mathematics achievement. Suppose, for the sake of argument, that frequency of math drills has no effect on achievement levels among students at the same level of prior mathematics achievement – that is, math drills and NAEP achievement level are conditionally independent, given prior achievement. If, as prior achievement goes down, the frequency of math drills goes up and NAEP achievement level goes down, then when we collapse over prior achievement, math drills and NAEP achievement level will appear to be negatively correlated; this is a version of Simpson's or Yule's paradox (Fienberg, 1980). Even if there is a positive association between math drills and NAEP achievement level within each level of prior achievement, this association can be wiped out or even reversed by collapsing.

For example, consider **Table 4**. Here, students have been cross-classified according to meeting or not meeting an achievement standard on a post-test, experiencing or not experiencing math drills, and total score on a short

Table 4 Cross-classification of math drills (yes/no), pretest score (0–4), and meeting standard (yes/no) for 2694 hypothetical students

	<i>Pretest = 0</i>		<i>Pretest = 1</i>		<i>Pretest = 2</i>		<i>Pretest = 3</i>		<i>Pretest = 4</i>		<i>All students</i>	
	<i>Meet</i>	<i>Standard</i>	<i>Meet</i>	<i>Standard</i>	<i>Meet</i>	<i>Standard</i>	<i>Meet</i>	<i>Standard</i>	<i>Meet</i>	<i>Standard</i>	<i>Meet</i>	<i>Standard</i>
<i>Drill</i>	<i>Yes</i>	<i>No</i>	<i>Yes</i>	<i>No</i>	<i>Yes</i>	<i>No</i>	<i>Yes</i>	<i>No</i>	<i>Yes</i>	<i>No</i>	<i>Yes</i>	<i>No</i>
Yes	93	19	150	88	212	170	153	177	53	180	661	634
No	300	87	197	168	170	199	79	133	11	55	757	642

The far-right subtable collapses (sums) over pretest score groups.

pretest (0–4). In each 2×2 subtable (for pretest = 0, for pretest = 2, etc.) the association between math drill and meet standard is positive ($OR > 1.4$ in each subtable). However, when we collapse (sum) across pretest scores to obtain a single 2×2 table for all students, the association becomes negative ($OR = 0.88$).

Common Odds Ratio and the CMH Procedure

The complete independence log-linear model [1][2][3] provides an unacceptably poor fit to Table 4 ($G^2 = 624$ on 13 df), but the ‘no second-order interaction’ model, [12][13][23], fits quite well ($G^2 = 0.009$ on 4 df). The absence of the three-way interaction means that the odds ratio between math drill and meets standard in each pretest subtable is independent of the pretest score. Therefore, in estimating this common odds ratio and testing independence between math drill and meet standard, we should pool data across pretest score groups to increase estimation precision and statistical power. However, as shown in Table 4, we cannot pool by simply summing cell counts across these groups.

Instead, we apply the CMH procedure, which provides both an estimate of the common odds ratio, and a chi-squared test of conditional independence of math drill and meets standard, given pretest score (i.e., a test of the null hypothesis that the common odds ratio equals 1). The CMH estimate of the common odds ratio pools the numerator and denominator of eqn [4] separately

$$OR_{MH} = \frac{\sum_{k=1}^K n_{11k}n_{22k}/n_{..k}}{\sum_{k=1}^K n_{12k}n_{21k}/n_{..k}}$$

where n_{ijk} is the observed count at level i of math drill, j of meets standard, and k of pretest score, and $n_{..k}$ is the number of students in pretest score group k . We compute confidence intervals for OR_{MH} using standard errors for $\log(OR_{MH})$ and a test for whether $OR_{MH} = 1$ by comparing the square of $\log(OR_{MH})$ divided by its standard error to values of the X^2 distribution on 1 df. (We can accomplish a similar test using a conditional likelihood-ratio test for the model [23][13] given the model [12][23][13], and the difference between the corresponding G^2 values. The CMH test for conditional independence is, however, the uniformly most powerful test (see Holland and Thayer, 1988).

Applying the CMH procedure to Table 4, we find strong evidence against the model of conditional independence of math drill with meeting standard given pretest score) is rejected ($X^2 = 18$ on 1 df), and we estimate the common odds ratio as 1.45, with 95% confidence interval (1.23, 1.72). There is a noticeable positive association between experiencing the math drills and meeting the standard on the post-test, for students in each pretest group.

Application to Differential Item Functioning (DIF) Analysis

The CMH procedure appears regularly in large-scale educational testing to assess whether test items function differently in different social groups. Let i represent the groups of interest, generally called the reference group ($i = 1$) and the focal group ($i = 2$), and let j represent correct ($j = 1$) or incorrect ($j = 2$) response to a test item that is suspected to function differently in the two groups. Finally, let k be the scores on an anchor test that is known or assumed not to function differentially in the two groups. Then, the CMH test of conditional independence is in fact a test of whether group membership (i) affects performance on the item (j) after controlling for students’ achievement level (k). Holland and Thayer (1988) make an important connection between the CMH procedure for DIF detection and item response theory (IRT) models, which we discuss below.

Logistic Regression

The general log-linear model for contingency tables, for example,

$$\log E(n_{ijkl}) = u + u_{1(i)} + u_{2(j)} + u_{3(k)} + u_{4(l)} + \dots + u_{12(ij)} + u_{23(jk)} + \dots$$

is an instance of the class of generalized linear models (GLMs; McCullagh and Nelder, 1989), since it expresses the mean of the response variable as a transformation of a linear model

$$E(Y) = g(X\beta) \quad [6]$$

where $Y = n_{ijkl}$ is the cell count, $g(x) = \exp(x)$ is the transformation or link function, X collects together

indicator variables for the levels of the cross-classifying variables, and β collects together the u -parameters. Three distributions – the Poisson, the multinomial, and the product multinomial – are commonly used as sampling distributions for contingency tables; fortunately, maximum-likelihood estimates and standard errors for log-linear models are the same under all three distributions (Bishop *et al.*, 1975; Fienberg, 1980).

Perhaps the most widespread GLM is the logistic regression model. For binary logistic regression, we consider a binary 0–1 response variable Y_i with mean $E(Y_i) = P(Y_i = 1) = p_i$ such that

$$\log\left(\frac{p_i}{1-p_i}\right) = X_i\beta,$$

such that the link function in eqn [6] is $g(x) = \exp(x)/(1 + \exp(x))$, and we use the binomial distribution as the sampling model.

Comparing Log-Linear Models with Logistic Regression

We can apply the logistic regression model to the data of **Table 4**, taking the response variable Y_{ij} to be 1 if a student with pretest score i and math drill level j meets the standard on the post-test, and 0 otherwise. The additive logistic model

$$\log\left(\frac{p_{ij}}{1-p_{ij}}\right) = v_0 + v_{1(i)} + v_{2(j)}$$

fits well, with $G^2 = 0.009$ on 4 df. The perceptive reader will recognize that this is the same likelihood-ratio statistic value as the log-linear model of ‘no three-way interactions’ [12][13][23], which we used to establish that there was a common odds ratio in the section titled ‘Common odds ratio and the CMH procedure.’ This is no accident: a logistic regression model applied in this way to a contingency table is equivalent to the log-linear model with (1) a full interaction for all factors on the right-hand side of the logistic regression model; and (2) an interaction of the response with each term on the right-hand side. Hence, letting factor 3 be the meets standard, the additive logistic regression model above is equivalent to the model [12][13][23] which is exactly the model of no second-order interaction.

At each fixed level i of pretest score, the log-odds-ratio under the additive model for meeting the standard on the post-test between someone who did ($j = 1$) and did not ($j = 2$) experience the math drill condition is

$$\begin{aligned} \log\left(\frac{p_{i1}}{1-p_{i1}}\right) - \log\left(\frac{p_{i2}}{1-p_{i2}}\right) \\ = (v_0 + v_{1(i)} + v_{2(1)}) - (v_0 + v_{1(i)} + v_{2(2)}) \\ = v_{2(1)} - v_{2(2)} \end{aligned}$$

We estimate this to be 0.37 with standard error 0.09, clearly a significant positive association between math drill and meets standard on the post-test. This is, as we would expect, identical to the estimate of the common log-odds-ratio under the log-linear model [12][13][23].

If we were concerned with the possibility of differing odds ratios in different pretest score groups, we could explore this with the interactive logistic regression model

$$\log\left(\frac{p_{ij}}{1-p_{ij}}\right) = v_0 + v_{1(i)} + v_{2(j)} + v_{12(ij)} \quad [8]$$

which is the same as the saturated model [123]. A more parsimonious model would be

$$\begin{aligned} \log\left(\frac{p_i}{1-p_i}\right) = \tau_0 + \tau_1(\text{pretest})_i + \tau_2(\text{mathdrill})_i \\ + \tau_3(\text{pretest})_i \times (\text{mathdrill})_i \end{aligned}$$

where $(\text{pretest})_i$ is student i ’s pretest score (0–4); and $(\text{math drill})_i = 1$ if student i experienced the math drill condition and 0 otherwise. This model, which treats pretest score as an interval variable instead of an ordinal one, does not fit the data in **Table 4** particularly well ($G^2 = 24.78$ on 6 df). In any case, we could estimate odds ratios that vary from one pretest score group to the next from either model [8] or [9] using calculations analogous to eqn [7].

Application to DIF Analysis

The logistic regression approach is also used to assess DIF in large-scale educational testing. The usual approach is to use a model analogous to eqn [9]

$$\begin{aligned} \log\left(\frac{p_i}{1-p_i}\right) = \tau_0 + \tau_1(\text{anchortest})_i + \tau_2(\text{group})_i \\ + \tau_3(\text{anchortest})_i \times (\text{group})_i \end{aligned}$$

where p_i is student i ’s probability of getting the suspect item correct, $(\text{anchor test})_i$ is the score on the anchor test for student i , and $(\text{group})_i$ is student i ’s group membership ($i = 0$ for the reference group, and $i = 1$ for the focal group). The submodel $\tau_2 = \tau_3 = 0$ corresponds to no DIF, $\tau_3 = 0$ corresponds to uniform DIF, with the magnitude of the DIF measured by an effect size based on the log-odds-ratio τ_2 , and finally the full model corresponds to nonuniform DIF, that is, DIF that varies with the anchor test score.

Latent Variable Models of Association

Latent variable models provide an alternative to hierarchical log-linear models for examining dependence structure among categorical random variables. In the typical

latent variable model, we posit an unobserved variable θ_i for each individual i in the study, and assume that observable categorical variables are conditionally independent given θ_i : calling θ factor 0, and the observable variables factors 1, 2, 3, ..., \mathcal{J} , we assume the complete data model (01)(02) ... (0 \mathcal{J}). Conditional independence given the unobservable factor 0 is called local independence in the latent variable literature. We can only observe the categorical variables collapsed over θ , inducing dependence among the observed variables, just as in **Table 4**. This usually leads to a more parsimonious interpretation for the interactions among the \mathcal{J} observable variables than would hierarchical log-linear models.

IRT Models

One of the most widely used and successful classes of latent variable models in educational statistics is the class of IRT models. Here, θ_i is a continuous variable representing student i 's proficiency in an academic area, and $X_{i1}, \dots, X_{i\mathcal{J}}$ are the student's scored responses to a set of \mathcal{J} test items in that area. When the responses are scored 0 for a wrong answer and 1 for a correct answer, we have a simple binary model

$$P(X_{ij} = 1 | \theta_i, \beta_j) = P(\theta_i, \beta_j)$$

where β_j are parameters describing the probability of correct response at a fixed level θ_i . Collapsing the conditional independence model (01)(02) ... (0 \mathcal{J}) over θ (factor 0) leads to a submodel of (123 ... \mathcal{J}),

$$P(x_1, \dots, x_{\mathcal{J}} | \beta_1, \dots, \beta_{\mathcal{J}}) = \int \prod_{j=1}^{\mathcal{J}} P(\theta, \beta_j)^{x_j} (1 - P(\theta, \beta_j))^{1-x_j} dF(\theta) \quad [10]$$

where the product inside the integral represents conditional independence, analogous to independence in the separate 2×2 subtables in **Table 4** (see also eqn [3] above) and the integral itself corresponds to summing across these subtables. Although this model allows for interactions of all orders; it only depends on the parameters $\beta_1, \dots, \beta_{\mathcal{J}}$ and is therefore typically much more parsimonious than the saturated model (123 ... \mathcal{J}), which has $2^{\mathcal{J}}$ parameters.

Because $2^{\mathcal{J}}$ is typically large, relative to N , there will be many zero counts in cells with positive probability under the model, known as sampling zeros. The IRT model effectively smooths over these empty cells, such that it is less sensitive to zero counts than typical hierarchical log-linear models. In case each $P(\theta, \beta_j)$ is nondecreasing in θ , the X_j 's under model (10) will exhibit a particularly strong form of positive dependence, called conditional association (Holland and Rosenbaum, 1986). This can be used to assess fit of the model (10) without knowing the details of the functions $P(\theta, \beta_j)$ or the distribution $dF(\theta)$.

The Rasch Model, Quasi-Symmetry, and DIF Analysis

The special case of the Rasch (1980) model

$$P(X_{ij} = 1 | \theta_i, \beta_j) = \frac{e^{(\theta_i - \beta_j)}}{1 + e^{\theta_i - \beta_j}} \quad [11]$$

provides two important connections between IRT models and log-linear models. For the first connection, Holland (1990) has shown that, for the Rasch model, the logarithm of eqn [10] becomes

$$\log P(x_1, \dots, x_{\mathcal{J}} | b_1, \dots, b_{\mathcal{J}}) = - \sum_{j=1}^{\mathcal{J}} x_j \beta_j + G(x_+; \beta_1, \dots, \beta_{\mathcal{J}})$$

where $x_+ = \sum_{j=1}^{\mathcal{J}} x_j$. This corresponds to the log-linear model

$$\log E(n_{x_1, \dots, x_{\mathcal{J}}}) = \alpha_0 + \sum_{j=1}^{\mathcal{J}} \alpha_j x_j + \sum_{k=0}^K \gamma_k I_k$$

for the counts in the $2^{\mathcal{J}}$ table cross-classifying students' scored responses to the \mathcal{J} test items, where $\alpha_j = -\beta_j$, $\gamma_k = G(k; \beta_1, \dots, \beta_{\mathcal{J}})$, and $I_k = 1$ if $x_+ = k$ and 0 otherwise. This model contains all main effects, and interactions of all orders, but the interactions are constrained to be symmetric: all two-way interactions are equal to γ_2 , all three-way interactions are equal to γ_3 , etc., corresponding to the model of quasi-symmetry. But there are also constraints on the γ_k 's: they are functions of the β_j 's, and obey the order constraints of a sequence of log-moments of the distribution of a non-negative random variable.

For the second connection, suppose we suspect that item \mathcal{J} functions differently in a reference group and a focal group of examinees, but the items 1, 2, ..., $\mathcal{J} - 1$ function the same way in both groups. We could model this in the Rasch model, using one item parameter $\beta_{\mathcal{J}\text{R}}$ for item \mathcal{J} in the reference group and a different parameter $\beta_{\mathcal{J}\text{F}}$ in the focal group, in [11]. The odds ratio – conditional on θ – for correct response to this item between the two groups is

$$OR = \exp(\beta_{\mathcal{J}\text{F}} - \beta_{\mathcal{J}\text{R}})$$

which is invariant across levels of θ . This common odds ratio represents uniform DIF, that is, a constant shift in the location of the item response curve under the Rasch model. Since the total score X_+ is a sufficient statistic for θ in the Rasch model, the MH estimate of the common log-odds ratio, using X_+ as the stratifying variable, is directly interpretable as an estimate of the group difference in difficulty: $\beta_{\mathcal{J}\text{F}} - \beta_{\mathcal{J}\text{R}}$ (Holland and Thayer, 1988; Zwick, 1990).

Other Latent Variable Models

Other latent variable models have become popular for parsimonious and interpretable analysis of contingency table data as well. For example,

- Cognitive diagnosis models (CDMs) are a class of constrained latent class analysis (LCA) models. CDMs begin with a latent variable $\theta_i = (\theta_{i1}, \dots, \theta_{ik})$, where each $\theta_{ik} = 1$ if student i possesses cognitive attribute k , and 0 otherwise. This is equivalent to $C = 2^K$ latent classes, in which each class c is identified with a unique sequence of cognitive attribute indicators $\theta^{(c)} = (\theta_1(c), \dots, \theta_K(c))$. The response probability $P(X_{ij} = 1 | \theta_i, \beta_j) = P(\theta_i, \beta_j)$ is then parametrized in terms of the $\theta_k^{(c)}$'s; for example, a simple conjunctive model (requiring all skills needed for a task to be present, to maximize success on that task) would be

$$P(\theta_i, \beta_j) = \prod_{k=1}^K \left[(1 - s_{jk})^{\theta_k^{(c)}} g_{jk}^{1-\theta_k^{(c)}} \right]^{Q_{jk}} \quad [12]$$

where $Q_{jk} = 1$ if test item j requires cognitive attribute k , and 0 otherwise, and $\beta_j = (g_j, s_j)$. Junker and Sijtsma (2001) provide a brief technical review of some simple CDMs. For a broader overview, see the special issue of *Journal of Educational Measurement* edited by DiBello and Stout (2007).

- The grade of membership (GoM) model can be viewed as a continuous-variables reformulation of the LCA model. The basic LCA model for an individual i in class c , with j th binary response X_{ij} can be written

$$P(X_{ij} = 1 | \theta_i = (0, \dots, 0, 1, 0, \dots, 0)) = \lambda_{jc}$$

where 1 appears in the c th position of the vector $\theta_i = (\theta_{i1}, \dots, \theta_{iC})$, or equivalently

$$P(X_{ij} = 1 | \theta_i) = \sum_{c=1}^C \lambda_{jc} \theta_{ic}$$

In the GoM model, this is a response probability for pure-type c . The GoM model then generalizes this structure by allowing θ_i to be not just a sequence of C 0's and 1's summing to unity, but rather any sequence of C nonnegative weights, summing to unity. Thus, each response probability is a mixture of pure-type probabilities, with mixing proportions equal to the individual's so-called GoM score $\theta_i = (\theta_{i1}, \dots, \theta_{iC})$. The θ_{ic} 's are the individual's grade or degree of membership in each pure type; in this sense the GoM model is like a soft-clustering model. Erosheva *et al.* (2007) show that each GoM model corresponds to an LCA model with a larger number of latent classes but provides a more parsimonious and interpretable representation than the corresponding LCA model.

Causal Inference

D B Rubin, Harvard University, Cambridge, MA, USA

A Framework for Causal Inference – Basic Building Blocks

The framework for causal inference that is discussed here is now commonly referred to as the Rubin Causal Model (RCM; Holland, 1986), for a series of articles written in the 1970s (Rubin, 1974, 1976, 1977, 1978, 1980). Other approaches to causal inference, such as graphical ones (e.g., Pearl, 2000), are conceptually less satisfying, for reasons discussed, for instance, in Rubin (2004b, 2005). The presentation here is essentially a brief and relatively nontechnical version of that given in Rubin (2006).

For causal inference, there are several basic building blocks. A unit is a physical object, for example, a person, at a particular point in time. A treatment is an action that can be applied or withheld from that unit. We focus on the case of two treatments, although the extension to more than two treatments is simple in principle but not necessarily so with real data. Associated with each unit are two potential outcomes: the value of an outcome variable Y (e.g., test score) at a point in time t when the active treatment (e.g., new educational program) is used at an earlier time t_0 , and the value of Y at time t when the control educational program is used at t_0 . The objective is to learn about the causal effect of the application of the active treatment relative to the control (treatment) on Y . Formal notation for this meaning of a causal effect first appeared in Neyman (1923) in the context of randomization-based inference in randomized experiments. Let W indicate which treatment the unit received: $W = 1$ the active treatment, $W = 0$ the control treatment. Moreover, let $Y(1)$ be the value of Y if the unit received the active version, and $Y(0)$ the value if the unit received the control version. The causal effect of the active treatment relative to its control version is the comparison of $Y(1)$ and $Y(0)$ – typically the difference, $Y(1) - Y(0)$, or perhaps the difference in logs, $\log[Y(1)] - \log[Y(0)]$, or some other comparison, possibly the ratio. The fundamental problem for causal inference is that, for any individual unit, we can observe only one of $Y(1)$ or $Y(0)$, as indicated by W ; that is, we observe the value of the potential outcome under only one of the possible treatments, namely the treatment actually assigned, and the potential outcome under the other treatment is missing. Thus, inference for causal effects is a missing-data problem – the “other” value is missing. Of importance in educational research, the gain score for a unit, posttest

minus pretest, measures a change in time, and so is not a causal effect.

We learn about causal effects using replication, which involves the use of more than one unit. The way we personally learn from our own experience is replication involving the same physical object (me or you) with more units in time, thereby having some observations of $Y(0)$ and some of $Y(1)$. When we want to generalize to units other than ourselves, we typically use more objects; that is what is done in social science experiments, for example, involving students and possible educational interventions, such as value-added assessment (e.g., Rubin *et al.*, 2004). Replication does not help without additional assumptions. The most straightforward assumption to make is the stable unit treatment value assumption (SUTVA; Rubin, 1980, 1990) under which the potential outcomes for the i th unit are determined by the treatment the i th unit received. That is, there is no interference between units (Cox, 1958) and there are no versions of treatments (Rubin, 1980). Then, all potential outcomes for N units with two possible treatments can be represented by an array with N rows and two columns, the i th unit having a row with two potential outcomes, $Y_i(0)$ and $Y_i(1)$, where each could, in principal, be a vector with many components. Obviously, SUTVA is a major assumption. Good researchers attempt to make such assumptions plausible by the design of their studies. For example, SUTVA becomes more plausible when units are isolated from each other, as when using, for the units, intact schools rather than students in the schools when studying an educational intervention, such as a smoking prevention program (e.g., see Peterson *et al.*, 2000).

In addition to (1) the vector indicator of treatments for each unit in the study, $W = \{W_i\}$, (2) the array of potential outcomes when exposed to the active treatment, $Y(1) = \{Y_i(1)\}$, and (3) the array of potential outcomes when not exposed, $Y(0) = \{Y_i(0)\}$, we have (4) an array of covariates $X = \{X_i\}$, which are, by definition, unaffected by treatment, such as age, race sex, or pretest scores, where the ‘pre’ means prior to the intervention, that is, before t_0 . Covariates can be used to help define causal estimands. All causal estimands involve comparisons of $Y_i(0)$ and $Y_i(1)$ on either all N units, or a common subset of units; for example, the average causal effect across all units that are female as indicated by their X_i , or the median causal effect for units with X_i indicating male and $Y_i(0)$ indicating failure on the posttest under the control treatment.

Under SUTVA, all causal estimands can be calculated from the matrix of scientific values with i th row: $(X_i, Y_i(1), Y_i(0))$. By definition, all relevant information is encoded in $X_i, Y_i(0), Y_i(1)$ and so the labeling of the N rows is a random permutation of $1, \dots, N$, and the matrix is row exchangeable. Covariates play a particularly important role in the analysis of observational studies for causal effects where they are also known as possible confounders or risk factors. In some studies, the units exposed to the active treatment differ in their distribution of covariates in important ways from the units not exposed. To see how this issue influences our formal framework, we must define the assignment mechanism, the probabilistic mechanism that determines which units receive the active version of the treatment and which units receive the control version.

The Assignment Mechanism – Motivating Examples

Even with SUTVA, inference for causal effects requires the specification of an assignment mechanism: a probabilistic model for how some units were selected to receive the active treatment and how other units were selected to receive the control treatment. We first illustrate this model in two trivial artificial examples, and then present formal notation for this model.

Consider a teacher who is considering one of two treatments to apply to each of eight students, a standard and a new one. This teacher is a great teacher and the treatment that is best for each student! When they are equally effective, a fair coin is tossed. **Table 1** gives both the hypothetical potential outcomes in test scores under each treatment for these students, and also their individual causal effects. The column labeled W shows which treatment each student received, $W_i = 0$ or $W_i = 1$ for the i th student.

Notice that the eight individual causal effects indicate that the typical student will do better with the standard

treatment (i.e., the control treatment): the average causal effect is two points in favor of the standard. However, the teacher, who is conducting ideal educational practice for the benefit of the students, reaches the opposite conclusion from an examination of the observed data: the students assigned the new treatment do, on average more than twice as well as the students assigned the control, with absolutely no overlap in their distributions!

What is wrong? The simple comparison of observed outcomes assumes that treatments were randomly assigned, rather than as they were, to provide maximal benefit to the students. More precisely, notice that the teacher, by comparing observed means of the outcome Y , is using the three observed values of $Y_i(1)$ to represent the five missing values of $Y_i(1)$, effectively imputing or filling in \bar{y}_1 , the observed mean of the $Y_i(1)$, for the five $Y_i(1)$ question marks, and analogously effectively filling in \bar{y}_0 for the three $Y_i(0)$ question marks. This process makes sense for point estimation if the three observed values of $Y_i(1)$ were randomly chosen from the eight values of $Y_i(1)$, and the five observed values of $Y_i(0)$ were randomly chosen from the eight values of $Y_i(0)$. However, under the actual assignment mechanism, it does not make sense. It would make much more sense under the actual assignment mechanism to impute the missing potential outcome for each student to be less than or equal to that student's observed potential outcome. The point here is simply that the assignment mechanism is crucial to valid inference about causal effects, and the teacher used a nonignorable assignment mechanism (defined shortly). With a posited assignment mechanism, it is possible to draw causal inferences; without one, it is impossible. It is in this sense that when drawing causal inferences, a model for the assignment mechanism is more fundamental than a model for the potential outcomes.

We next consider a classical paradox in educational research that is easily resolved with the simple ideas we have already presented, despite the controversy that the paradox engendered in some literatures. This example illustrates how important it is to keep this perspective clearly in mind when thinking about causal effects of interventions. Lord (1967) proposed the following example:

A large university is interested in investigating the effects on the students of the diet provided in the university dining halls and any sex differences in these effects. Various types of data are gathered. In particular, the weight of each student at the time of arrival in September and the following June are recorded.

The result of the study for the males is that their average weight is identical at the end of the school year to what it was at the beginning; in fact, the whole distribution of weights is unchanged, although some males lost weight and some males gained weight – the gains and losses exactly balance. The same thing is true for

Table 1 Perfect teacher

Potential outcomes		Observed data			
	$Y(0)$	$Y(1)$	W	$Y(0)$	$Y(1)$
	13	14	1	?	14
	6	0	0	6	?
	4	1	0	4	?
	5	2	0	5	?
	6	3	0	6	?
	6	1	0	6	?
	8	10	1	?	10
	8	9	1	?	0
True averages	7	5	Observed averages	5.4	11

the females. The only difference is that the females started and ended the year lighter on average than the males. On average, there is no weight gain or weight loss for either males or females. From Lord's description of the problem quoted above, the quantity to be estimated, the estimand, is the difference between the causal effect of the university diet on males and the causal effect of the university diet on females. That is, the causal estimand is the difference between the causal effects for males and females, the differential causal effect.

The paradox is generated by considering the contradictory conclusions of two statisticians. Statistician 1 observes that there are no differences between the September and June weight distributions for either males or females. Thus, statistician 1 concludes that

...as far as these data are concerned, there is no evidence of any interesting effect of diet (or of anything else) on student weight. In particular, there is no evidence of any differential effect on the two sexes, since neither group shows any systematic change (Lord, 1967: 305).

Statistician 2 looks at the data in a more sophisticated way. Effectively, he examines males and females with about the same initial weight in September, say a subgroup of overweight females (meaning simply above-average-weight females) and a subgroup of underweight males (analogously defined). He notices that these males tended to gain weight on average and these females tended to lose weight on average. He also notices that this result is true no matter what group of initial weights he focuses on. (Actually, Lord's statistician 2 used a covariance adjustment/regression adjustment.) Therefore the conclusion of statistician 2 is that, after controlling for initial weight, the diet has a differential positive effect on males relative to females because for males and females with the same initial weight, on average, the males gain more than the females.

Let us formulate the problem as advocated here. The units are the students, the time of application of treatment (the university diet) is September, and the time of the recording of the outcome Y is June; accept the stability assumption. The potential outcomes are June weight under the university diet $Y_i(1)$ and under the control diet $Y_i(0)$. The covariates are sex of students, male versus female, and September weight. However, the assignment mechanism has assigned everyone to the new treatment! There is no one, male or female, who is assigned to the control treatment. Hence, there is absolutely no purely empirical basis on which to estimate the causal effects, either raw or differential, of the university diet relative to the control diet. Lord has created partial confusion by making the problem complicated with the introduction of the covariates male/female and initial weight, and by using the observed variable notation, Y_{obs} , where $Y_{\text{obs},i} = W_i Y_i(1) + (1 - W_i) Y_i(0)$, which mixes up the science,

reflected here by $(Y_i(1), Y_i(0))$ and the assignment mechanism, reflected by W_i . For more statistical details of the resolution of this paradox, see Holland and Rubin (1983), and for earlier related discussion, see for example, Lindley and Novick (1981), or Cox and McCullagh (1982). However, the point here is that the paradox is immediately resolved through the explicit use of potential outcomes. In fact, either answer could be correct for causal inference depending on what we are willing to assume about the control diet, as elucidated by Holland and Rubin (1983).

The Assignment Mechanism – Formal Notation

A model for the assignment mechanism is needed for all forms of statistical inference for causal effects. Formally, the assignment mechanism gives the conditional probability of each vector of assignments given the covariates and potential outcomes:

$$\Pr(W|X, Y(0), Y(1)).$$

A specific example of an assignment mechanism is a completely randomized experiment with N units, where $n < N$ are assigned to the active treatment, and $N - n$ to the control treatment.

$$\Pr(W|X, Y(0), Y(1)) = 1/C_n^N \quad \text{if } \sum W_i = n \\ 0 \quad \text{otherwise}$$

An unconfounded assignment mechanism is free of dependence on either $Y(0)$ or $Y(1)$:

$$\Pr(W|X, Y(0), Y(1)) = \Pr(W|X).$$

With an unconfounded assignment mechanism, at each set of values of X_i that has a distinct probability of $W_i = 1$, there is effectively a completely randomized experiment. That is, if X_i indicates sex, with males having probability 0.2 of receiving the active treatment and females having probability 0.5 of receiving the active treatment, then essentially one randomized experiment is prescribed for males and another for females.

The assignment mechanism is probabilistic if each unit has a positive probability of receiving either treatment:

$$0 < \Pr(W_i = 1|X, Y(0), Y(1)) < 1,$$

where the unit level probabilities are known as propensity scores (Rosenbaum and Rubin, 1983). Unconfounded probabilistic assignment mechanisms often allow particularly straightforward estimation of causal effects from all perspectives, and these assignment mechanisms form the basis for inference for causal effects in more complicated situations, such as when assignment probabilities depend on covariates in unknown ways, or when there is noncompliance with the assigned treatment, or even

in observational (nonrandomized) studies. Unconfounded probabilistic assignment mechanisms are essentially generalized randomized experiments, and are called strongly ignorable (Rosenbaum and Rubin, 1983).

A confounded assignment mechanism is one that depends on the potential outcomes. A special class of possibly confounded assignment mechanisms is particularly important to Bayesian inference: ignorable assignment mechanisms (Rubin, 1978). Ignorable assignment mechanisms are defined by their freedom from dependence on any missing potential outcomes:

$$\Pr(W|X, Y(0), Y(1)) = \Pr(W|X, Y_{\text{obs}}).$$

Ignorable but confounded assignment mechanisms arise in practice, most commonly in sequential experiments, where the next (in time) unit's probability of being exposed to the active treatment depends on the success rate of those previously exposed to the active treatment versus the success rate of those exposed to the control treatment, as in play-the-winner designs (e.g., Efron, 1971). All unconfounded assignment mechanisms are ignorable, but not all ignorable assignment mechanisms are unconfounded (e.g., play-the-winner designs).

Modes of Causal Inference

There are two distinct forms of assignment-mechanism-based (or randomization-based) modes of causal inference: one due to Neyman (1923) and the other due to Fisher (1925). There is a third approach (Rubin, 1978), which is posterior predictive (Bayesian).

Fisher's approach is closely related to the mathematical idea of proof by contradiction. The first element in Fisher's mode is the null hypothesis, which is usually $Y_i(1) \equiv Y_i(0)$ for all units: the treatments have absolutely no effect on the potential outcomes. Under this null hypothesis, all potential outcomes are known from the observed values of the potential outcomes, Y_{obs} , because $Y(1) \equiv Y(0) \equiv Y_{\text{obs}}$. It follows that, under this null hypothesis, the value of any statistic, S , such as the difference of the observed averages for units exposed to treatment 1 and units exposed to treatment 0, $\bar{y}_1 - \bar{y}_0$, is known, not only for the observed assignment, but also for all possible assignments W . Suppose we calculate the value of S under each possible assignment (assuming the null hypothesis) and also calculate the probability of each assignment under the randomized assignment mechanism. Knowing the value of S for each W and its probability, we can then calculate the probability (under the assignment mechanism and the null hypothesis) that we would observe a value of S as unusual as, or more unusual than, the observed value of S , S_{obs} . Unusual is defined *a priori*, typically by how discrepant S_{obs} is from the typical values of S . This

probability is the plausibility (p -value or significance level) of the observed value of the statistic S under the null hypothesis: if the null hypothesis were true, the probability of S being as rare, or more rare, than S_{obs} .

Neyman's form of randomization-based inference can be viewed as drawing inferences by evaluating the expectations of statistics over the distribution induced by the assignment mechanism in order to calculate a confidence interval for the typical causal effect. First, an unbiased estimator of the causal estimand (the typical causal effect, e.g., the average) is created, and an unbiased, or upwardly biased, estimator of the sampling variance of that unbiased estimator is found (bias and sampling variance both defined with respect to the randomization distribution). Then, an appeal is made to the central limit theorem for the normality of the estimator over its randomization distribution, whence a confidence interval for the causal estimand is obtained.

With a data set that is not from a randomized study, we try to structure the problem so that we can conceptualize the data as having arisen from an underlying randomized experiment, and then estimate the assignment mechanism via the propensity scores for all the units. A key idea is that, like good experiments, good observational studies are designed, not simply found (Rubin, 2002, 2008). When designing an experiment, we do not have any outcome data, but we plan the collection, organization, and analysis of the data to improve our chances of obtaining valid, reliable, and precise causal answers. The same exercise should be done in an observational study: even if outcome data are available at the design stage, they should be set aside. As observational studies are rarely known to be unconfounded, we are concerned with the sensitivity of answers to unobserved covariates. The methods described by Rosenbaum (2002) are appropriate from the randomization-based perspective.

Posterior predictive (Bayesian) causal inference for causal effects requires a model for the underlying data, $\Pr(X, Y(0), Y(1))$, and this is where science enters. A virtue of the RCM framework is that it separates science – a model for the underlying data, from what we do to learn about science – the assignment mechanism, $\Pr(W|X, Y(0), Y(1))$. This approach directly and explicitly confronts the missing potential outcomes, $Y_{\text{mis}} = \{Y_{\text{mis},i}\}$, where $Y_{\text{mis},i} = W_i Y_i(0) + (1 - W_i) Y_i(1)$. The perspective takes the specification for the assignment mechanism and the specification for the underlying data, and derives the posterior predictive distribution of Y_{mis} , that is, the distribution of Y_{mis} given all observed values:

$$\Pr(Y_{\text{mis}}|X, Y_{\text{obs}}, W).$$

From this distribution and the observed values of the potential outcomes, the observed assignments, and observed covariates, the posterior distribution of any causal effect can,

in principle, be obtained. This conclusion is immediate if we view the above posterior predictive distribution as specifying how to take a random draw of Y_{mis} . Once a value of Y_{mis} is drawn, any causal effect can be directly calculated from the drawn value of Y_{mis} and the observed values of X and Y_{obs} . Repeatedly drawing values of Y_{mis} and calculating the causal effect for each draw generates the posterior distribution of the desired causal effect. Thus, as in Rubin (1978), we can view causal inference entirely as a missing data problem, where we multiply impute (Rubin, 1987, 2004a) the missing potential outcomes to generate a posterior distribution for the causal effects.

With ignorable treatment assignment, all that we need model is the science $\Pr(X, Y(0), Y(1))$, and we can ignore the assignment mechanism. A strength of this model-based approach is that it allows us to conduct causal inference by predicting the missing potential outcomes from observed values. The problem with this approach is the need to specify the distribution $\Pr(X, Y(0), Y(1))$, which sometimes can implicitly involve extrapolations that are extremely unreliable. More details of this approach are beyond the scope of this article, but can be found in, for example, Rubin (2006). With nonignorable treatment assignment, the simplifications previously described do not follow in general, and the analysis typically becomes far more difficult and speculative.

Complications

There are many complications that occur in real-world studies for causal effects, many of which can be handled much more flexibly with the Bayesian approach than with randomization-based methods. Of course, the models involved, including associated prior distributions, can be very demanding to formulate in a practically reliable manner. In addition, Neymanian evaluations are still important.

Most of the field of classical experiment design is devoted to issues that arise with more than two treatment conditions (e.g., Kempthorne, 1952; Cochran and Cox, 1957).

Missing data, due perhaps to unit dropout or machine failure, can complicate analyses more than one would expect based on a cursory examination of the problem. Methods such as multiple imputation (Rubin, 1987, 2004a), the expectation-maximization (EM) algorithm (Dempster *et al.*, 1977), data augmentation (Tanner and Wong, 1987), and the Gibbs sampler (Geman and Geman, 1984) are fully compatible with the Bayesian approach to causal inference outlined in the section titled 'Modes of causal inference'. Gelman *et al.* (2003) provide guidance on many of these issues from the Bayesian perspective.

Another complication, common when the units are people, is noncompliance (e.g., as in Sommer and Zeger, 1991).

Early work related to this issue can be found in economics (e.g., Tinbergen, 1930; Haavelmo, 1944) and elsewhere (e.g., Zelen, 1979; Bloom, 1984). Much progress has been made in recent years on this topic (e.g., Baker, 1998; Baker and Lindeman, 1994; Goetghebeur and Molenberghs, 1996; Angrist *et al.*, 1996; Imbens and Rubin, 1997; Little and Yau, 1998; Hirano *et al.*, 2000).

Further complications include truncation due to death (Rubin, 2000, 2004b; Zhang and Rubin, 2003; Zhang *et al.*, 2007). In the real world, complications typically do not appear simply one at a time. For example, a randomized experiment in education evaluating school choice suffered from missing data in both covariates and longitudinal outcomes; besides, the outcome was multicomponent at each point in time; in addition, it suffered from noncompliance that took several levels because of the years of school, as discussed, for example, Barnard *et al.* (2003) in the context of the school choice example.

Many of the above complications can be viewed as special cases of principal stratification (Frangakis and Rubin, 2002). This appears to be an extremely fertile area for research and application of Bayesian methods for causal inference, especially using modern simulation methods (see, e.g., Gilks *et al.*, 1995).

Cluster Analysis: Overview

S Landau, King's College London, London, UK

I Chis Ster, University College London, London, UK

The old idea of sorting similar things into groups underlies all aspects of human activity. For example, languages can be thought of as classification systems where words are used to describe types of events, objects, and people encountered. In addition to being a basic human conceptual activity, classification is fundamental to many branches of science with prominent examples being animal or plant taxonomies informing evolutionary theories in biology, or groupings of elements according to their chemical properties influencing research on the structure of the atom. In the social sciences, including education, it would typically be people that are to be grouped to identify patterns of behavior, achievement, etc.

Numerical methods aimed at discovering groups in data are referred to as cluster analysis. The groups can be sets of objects (individuals, countries, animals, chemical elements, etc.) or sets of variables. It also needs to be emphasized that cluster analysis is aimed at uncovering as-yet-unknown groups of objects; with analogous concepts being unsupervised pattern recognition or numerical taxonomy. In contrast, discriminant analysis or supervised pattern recognition aims to establish rules that classify objects into classes that are known *a priori* based on a set of observable characteristics. Finally, cluster analysis is an exploratory technique. Its primary aim is not to infer anything about population parameters as most statistical methods do – but rather to suggest groupings that might form the basis of future hypotheses to be investigated.

Cluster analysis techniques themselves can be broadly grouped into three classes labeled hierarchical clustering, optimization clustering, and model-based clustering. They operate either directly on a matrix of scores on a number of variables for a set of objects to be classified, or on a matrix of distances or similarities between the objects.

Proximity Measures

Ideally, clusters should be internally cohesive structures that are isolated from each other. To judge this adequacy criteria are needed that encapsulate the concepts of cluster homogeneity (cohesion) and separation (isolation). Such measures can be derived from a matrix of object distances or (dis)similarities; more generally referred to as proximities.

Let \mathbf{X} denote the usual $n \times p$ multivariate data matrix containing the data values describing each object to be clustered,

$$\mathbf{X} = \begin{bmatrix} x_{11} & x_{12} & \cdots & x_{1p} \\ x_{21} & \cdots & \cdots & x_{2p} \\ \vdots & \vdots & \vdots & \vdots \\ x_{n1} & \cdots & \cdots & x_{np} \end{bmatrix}$$

That is, the entry x_{ij} gives the value for the j th variable of the i th object. This is a two-mode matrix indicating that the rows and columns correspond to different things. For a raw data matrix containing only categorical variables, similarity measures are typically used. The similarity coefficient s_{ik} between objects i and k is one if both objects have identical values for all variables and zero if the two objects differ maximally for all variables. (The corresponding dissimilarity is then simply $d_{ik} = 1 - s_{ik}$.) In the binary case, similarity measures arise from a cross-classification of the counts of matches and mismatches of the p variables. **Table 1** shows some possible similarity measures. A multitude of measures has been proposed largely due to the uncertainty as to how to deal with the count of zero-zero matches (for a comprehensive list see Gower and Legendre (1986)). For categorical variables with more than two levels, similarities are typically calculated by allocating a score $s_{ik,j}$ of zero or one to each variable j , depending on whether the two objects i and k are the same on that variable and then simply averaging to give $s_{ik} = (1/p) \sum_j s_{ik,j}$. For a raw data matrix containing only continuous variables, proximities are typically expressed as distances (dissimilarity measures that fulfill the metric inequality); see **Table 2** for some possible measures. The Euclidean distance and the city block distance are appealing choices because of their geometric interpretation as physical distances between p -dimensional points with the latter traveled in rectilinear configuration.

As an example, consider applying the Euclidean distance measure to the protein consumption data in **Table 3**. The consumption for 25 European countries is measured in grams of protein food per day. Clearly, if we were to calculate distances on the raw data, these would be dominated by the variables relating to products generally eaten in larger quantities, such as cereals. We therefore standardize the variables to unit variance before applying the distance measure, a technique sometimes referred to as autoscaling. **Table 4** shows the resulting distance matrix (a one-mode matrix).

Finally, there are a number of approaches for constructing proximities for mixed-mode data – data in

which some variables are continuous and others are categorical. A simple approach is to construct an appropriate proximity matrix for each variable type submatrix and then to combine the measures.

Returning to our objective of wanting to measure the adequacy of a clustering on the basis of proximities, there are two basic approaches to defining intergroup proximities: (1) define the proximity by a suitable summary of the proximities between individuals from either group, or (2) represent each group by a typical observation and measure the proximity between these centers. Suitable summaries for (1) are the nearest neighbor distance, the furthest neighbor distance, or the average distance. Under approach (2), groups might be represented by, for example, the mean over the objects for each variable (continuous variables only), the so-called centroid, or the object that has the smallest average dissimilarity to all other group members (the medoid).

Hierarchical Clustering

Members of this class of clustering techniques produce a nested sequence of partitions by merging (or dividing)

Table 1 Similarity measures for binary data

Counts of binary outcomes for two individuals Individual <i>i</i>				
Individual <i>j</i>	Outcome	1	0	Total
	1	<i>a</i>	<i>b</i>	<i>a + b</i>
	0	<i>c</i>	<i>d</i>	<i>c + d</i>
	Total	<i>a + c</i>	<i>b + d</i>	<i>p = a + b + c + d</i>
Similarity measures				
Measure	Formula			
Matching coefficient	$s_{ij} = (a + d)/(a + b + c + d)$			
Jaccard coefficient	$s_{ij} = a/(a + b + c)$			
Rogers and Tanimoto	$s_{ij} = (a + d)/[a + 2(b + c) + d]$			
Sokal and Sneath	$s_{ij} = a/[a + 2(b + c)]$			
Gower and Legendre I	$s_{ij} = (a + d)/[a + \frac{1}{2}(b + c) + d]$			
Gower and Legendre II	$s_{ij} = a/[a + \frac{1}{2}(b + c)]$			

Table 2 Distance measures for continuous data

Measure	Formula
Euclidean distance	$d_{ij} = \left(\sum_{k=1}^p (x_{ik} - x_{jk})^2 \right)^{1/2}$
City block distance	$d_{ij} = \sum_{k=1}^p x_{ik} - x_{jk} $
Minkowski distance	$d_{ij} = \left(\sum_{k=1}^p (x_{ik} - x_{jk})^r \right)^{1/r} \quad (r \geq 1)$
Canberra distance	$d_{ij} = \begin{cases} 0 & \text{for } x_{ik} = x_{jk} = 0 \\ \sum_{k=1}^p x_{ik} - x_{jk} / (x_{ik} + x_{jk}) & \text{for } x_{ik} \neq 0 \text{ or } x_{jk} \neq 0 \end{cases}$

clusters. At each stage of the sequence, the new partition is optimally merged (or divided) from the previous partition according to some adequacy criterion. In the end, the sequence of partitions ranges from a single cluster containing all the individuals to *n* clusters containing a single individual. The whole series of partitions is most conveniently described by a tree display called the dendrogram (see later examples). Agglomerative hierarchical clustering proceeds by a series of successive fusions of the *n* objects into groups. In contrast, divisive hierarchical methods divide the *n* individuals successively into finer groups. Divisive methods are not commonly used due to computational problems; for more details see Everitt *et al.* (2001).

A variety of agglomerative techniques exist reflecting the different ways in which intergroup dissimilarities can be defined. For example, merging two clusters when their nearest neighbor distance is minimal leads to an agglomerative procedure called single linkage. Similarly, the use of the furthest neighbor distance or the average distance leads to complete and average linkage, respectively. To describe the agglomerative process, complete linkage will be applied to the first five countries in **Table 3** using the Euclidean distances shown as the shaded area in **Table 4**. Initially, there are five clusters all containing a single country (partition 1). The first step is to combine the closest pair of countries. From **Table 4** this is seen to be Austria and Czechoslovakia (partition 2). The distances between Albania, Bulgaria, and Belgium and the cluster (Austria and Czechoslovakia) need to be evaluated next. Based on the furthest neighbor distance this is found as: $d_{\text{new country, cluster}} = \max(d_{\text{new country, Austria}}, d_{\text{new country, Czechoslovakia}})$. After these new distances are calculated, the smallest value is again used to decide which clusters should be merged; here Belgium and (Austria, Czechoslovakia) are fused (partition 3). The next stage involves evaluating the furthest neighbor distances between clusters [(Austria, Czechoslovakia), Belgium], Albania and Bulgaria. This leads to Albania and Bulgaria being combined (partition 4) and then in the final step [(Austria, Czechoslovakia), Belgium] and (Albania,

From Hand, D. J., Daly, F., McConway, K., Lunn, D., and Ostrowsky, E. (1994). *A Handbook of Small Data Sets*. London: Chapman and Hall.

Bulgaria) are fused to become a single cluster (partition 5). The fusion process is described graphically by the dendrogram in **Figure 1** with the y -axis showing the distance at which clusters are fused. (Note that the display is not unique; e.g., (Albania, Bulgaria) or [Belgium, (Austria, Czechoslovakia)] can be flipped.) A popular agglomerative method for continuous data which measures cluster adequacy by evaluating distances between cluster centroids is Wards method. The approach merges clusters if the sum of the squared dissimilarities to the cluster centroid (a measure of cohesion) is minimal across all possible merging choices. **Figure 2** shows results of applying single linkage (a), complete linkage (b) and Ward's method (c) to the full distance matrix from **Table 4**. Different distances produce different cluster solutions. A similarity may be observed between complete linkage and Ward's method, but the single linkage solution looks rather different.

Users need to be aware that partitions obtained by hierarchical clustering are irrevocable in the sense that once clusters have been combined in an agglomerative procedure they cannot be split up again. This means that not all possible partitions are evaluated which, while computationally convenient, may mean that an optimal partition is missed. Second, the method may not take account of the cluster structure properly. For example, single linkage is known to be prone to chaining, the

tendency for new points to join the previous cluster in a chain-like fashion. This is what appears to have happened in **Figure 2(a)**. In contrast, complete linkage is known to produce compact clusters which may not always reflect the true data structure either. Efforts have been made to define properties that would be useful for hierarchical cluster methods. For example, point proportionality refers to replication of points not altering the boundaries of partitions. The monotone property, which states that the numerical values of the proximities are unimportant in that only their ranking matters for the clustering, might also be desirable. Single linkage and complete linkage, which otherwise are problematic, possess these properties; see Everitt *et al.* (2001).

Optimization Clustering

In contrast to hierarchical clustering methods optimization clustering methods aim to evaluate the adequacy of all possible partitions of a set of objects into k clusters. For the moment, we consider the number of clusters k to be known. The basic idea behind these methods is that associated with each partition of the n objects into the required number of groups k is an index $c(n, k)$, the value of which is to be optimized. Differences between the clustering methods in this class arise because of the variety of

criteria that might be optimized. In addition, optimization clustering is a computing-intensive process since the number of necessary evaluations soon becomes very large as the number of clusters and/or the sample size increases. Thus, even with today's computers complete enumeration is not possible and consequently different algorithms have been suggested to optimize the same cluster criterion.

Cluster criteria can be defined on the basis of the proximity matrix or on the basis of the raw data matrix. When using the proximity matrix the criteria tend to define the lack of homogeneity for a single group (e.g., by the maximum dissimilarity between two objects from the group) and then the lack of homogeneity of a partition by suitably aggregating over the groups (e.g., by using a weighted sum over the groups). A number of algorithms for optimizing such cluster criteria were proposed by Kaufman and Rousseeuw (1990), with perhaps the most popular one being the partitioning around medoids (PAM) algorithm which minimizes criterion $c_{\text{PAM}}(n, k) = \sum_{m=1}^k \sum_{i=1}^{n_m} d(\mathbf{x}_{im}, \text{medoid}_m)$, the sum of the dissimilarities between the objects with p -dimensional data vectors \mathbf{x}_{im} , $m \in \{1, \dots, k\}$, $i \in \{1, \dots, n_m\}$ and their cluster medoids. As an example, consider 1993 data from 705 American colleges and universities on student intake, cost, and learning environment published by US News and World Report magazine in 1995. The data set is available at the math forum data collection website. Here, we have selected nine typical variables as shown in Table 5 and use 705 colleges with complete information on these variables. The college sample is presented graphically in Figure 3. This raw data matrix was converted into a proximity matrix by calculating Euclidean distances. To overcome the unit of measurement problem, all variables were transformed so that they appeared to have symmetrical distributions (using ln and logit transformations) and then standardized to have sample mean 0 and standard deviation 1, before calculating distances. Application of the PAM algorithm provided the three clusters indicated in Figure 3. As PAM minimizes distances to the medoids, the latter represent

the best cluster summary. Table 6 shows that PAM cluster 1 consists of universities which enrol moderate numbers of students with a high proportion from the top 10% achievers, have the highest in-state tuition, smallest student-to-faculty ratio, and the highest proportion of graduates. Cluster 2 groups less selective universities that enrol the largest numbers of students, charge the least tuition fees, have a higher student-to-faculty ratio, and produce the smallest proportion of graduates. Cluster 3 contains less selective colleges with small enrolment numbers that charge moderate fees and have an average proportion of graduates.

Most cluster criteria derived from continuous data make use of a decomposition of the total dispersion matrix $\mathbf{T} = \sum_{m=1}^k \sum_{i=1}^{n_m} (\mathbf{x}_{im} - \bar{\mathbf{x}})(\mathbf{x}_{im} - \bar{\mathbf{x}})^T$, where $\bar{\mathbf{x}}$ is the p -dimensional vector of overall sample means for each variable, into

$$\mathbf{T} = \mathbf{W} + \mathbf{B} \quad [1]$$

where $\mathbf{W} = \sum_{m=1}^k \sum_{i=1}^{n_m} (\mathbf{x}_{im} - \text{centroid}_m)(\mathbf{x}_{im} - \text{centroid}_m)^T$ is the within-group dispersion matrix and $\mathbf{B} = \sum_{m=1}^k n_m (\text{centroid}_m - \bar{\mathbf{x}})(\text{centroid}_m - \bar{\mathbf{x}})^T$ is the between-group dispersion matrix. Most popular in this class of cluster criteria is minimization of $c_{\text{trace}}(n, k) = \text{trace}(\mathbf{W})$. This is equivalent to minimizing the sum of the squared Euclidean distances between the objects and their centroids. Popularity is due to most software packages containing a k-means algorithm, which minimizes this criterion by iteratively reallocating an object to another group if the object is nearer (in terms of Euclidean distance to the centroid) to the new group than its own. K-means clustering of the colleges into three groups using the transformed data produced the solution in Table 7, presenting similar substantive results to PAM. Similar to PAM, k -means clustering minimized distances in some sense and is not scale invariant. A scale-invariant alternative cluster criterion is minimization of $c_{\text{det}}(n, k) = \det(\mathbf{W})$. This cluster approach brings the practical benefit of not requiring the user to address the unit of measurement problem by standardization of variables or similar techniques. Both $\text{trace}(\mathbf{W})$ and $\det(\mathbf{W})$ clustering have a tendency to generate clusters of roughly the same size (in terms of number of objects) and of similar shape and volume. Further criteria have been suggested to overcome this; see Everitt *et al.* (2001). Finally, a note of caution: as all the so-called hill-climbing algorithms aim to find a global optimum without having to evaluate all possible partitions, it is important to check convergence against a global optimum, for example, by rerunning the algorithm with a new set of starting values.

Model-Based Clustering

Most cluster analysis methods are essentially heuristic methods in the sense that they do not make explicit

assumptions about the data-generating process. It is therefore impossible to infer from sample to population. Perhaps this presents no real difficulties to investigators involved in an initial exploration of their data where cluster analysis is only used to suggest hypothesis for future investigation. However, attempts have been made to develop a more acceptable statistical approach to the clustering problem, using what are known as finite mixture distributions (McLachlan and Peel, 2000).

Briefly, finite mixture densities are a family of probability density functions of the form

$$f(\mathbf{x}, \mathbf{p}, \boldsymbol{\theta}) = \sum_{m=1}^k p_m g_m(\mathbf{x}, \boldsymbol{\theta}_m) \quad [2]$$

where \mathbf{x} is a p -dimensional random variable and vectors $\mathbf{p}^T = [p_1, p_2, \dots, p_{k-1}]$ and $\boldsymbol{\theta} = [\boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \dots, \boldsymbol{\theta}_k]$ are parameter vectors. The $p_m \geq 0, m = 1, \dots, k; \sum_{m=1}^k p_m = 1$ are known as mixing proportions and the $g_m(\mathbf{x}, \boldsymbol{\theta}_m), m = 1, \dots, k$ are the component densities being parameterized by $\boldsymbol{\theta}_m$. The number of components forming the mixture is k .

Then, finite mixtures provide statistical models for cluster analysis if we assume that the objects within a cluster arise from one of k subpopulations with different multivariate distributions $g_m(\mathbf{x}, \boldsymbol{\theta}_m)$. The latter distributions may belong to the same family, but differ in the values they have for the parameters of the distributions or come from different families (e.g., Everitt and Bullmore, 1999). The mixing proportions and the parameters of the component densities can be estimated by maximum likelihood. This more formal statistical approach brings the advantage that one can develop cluster criteria whose optimization corresponds to maximizing the log-likelihood under a specified statistical model. This enables specification of the model assumptions under which a cluster criterion is expected to perform well.

Finally, having specified a suitable statistical model and estimated its parameters, the so-called model-based cluster analysis is typically performed by associating an object with a particular subpopulation (cluster) on the basis that this subpopulation maximizes the value of the estimated posterior probability:

$$\Pr(\text{object } i \text{ belongs to cluster } m \mid \mathbf{x}_i) = \frac{\hat{f}_m g_m(\mathbf{x}_i, \hat{\boldsymbol{\theta}}_m)}{f(\mathbf{x}_i, \hat{\mathbf{p}}, \hat{\boldsymbol{\theta}})} \quad [3]$$

over all possible subpopulations $m = 1, \dots, k$.

A common finite mixture model is based on multivariate normal densities with different mean vectors and possibly different covariance matrices. It can be shown that for unconstrained component covariance matrices $\boldsymbol{\Sigma}_m$, $m = 1, \dots, k$ maximization of the finite mixture likelihood is the same as minimizing criterion $c_{\text{unconstrained}}(n, k) = \prod_{m=1}^k [\det(\mathbf{W}_m/n_m^2)]^{n_m}$, where \mathbf{W}_m denotes the (sample) dispersion matrix for the n_m -dimensional m -th subpopulation. If the covariances can be assumed to be the same

Figure 3 Scatter plot of colleges' data in the space of the first two principal components (symbols and ellipses indicate the three-group PAM solution).

across subpopulations (though remain unknown), that is, $\boldsymbol{\Sigma}_m = \boldsymbol{\Sigma}$ for all m , the corresponding cluster criterion becomes $c_{\text{same cov}}(n, k) = \prod_{m=1}^k [\det(\mathbf{W}/n_m^2)]^{n_m}$. To explore the number of clusters present in the American colleges' data, **Figure 4** shows univariate distributions of the transformed data with overlaid densities. From this it appears that the number of visible subpopulations is 3 (see the three-peak distribution in **Figure 4(d)**). We therefore fitted a three-component multivariate normal mixture with constant (but unknown) component covariance matrices and used posterior probabilities to allocate cluster memberships. This leads to a cluster solution with similar interpretation to those obtained previously.

Finite mixtures with multivariate normal distributions have been widely used because of their computational convenience. However, alternatives have been suggested; for example, multivariate t-distributions for groups of observations with longer tails than normal or atypical observations (McLachlan and Peel, 2000). For binary data multivariate Bernoulli densities which arise by assuming, that within each cluster, the binary variables are independent from each other (the so-called conditional independence assumption), are typically used. The latter multivariate component densities define the classical latent class model (Lazarsfeld and Henry, 1968) and have also been referred to as discrete mixture distributions. An interesting example is reported by Aitkin *et al.* (1981) who fitted latent class models to observations on 38 binary variables describing teaching behavior observations made on 468 teachers. Teachers were allocated to two classes by maximizing their posterior probabilities. **Table 8** summarizes the results by displaying response probabilities for each of the 38 items and each of the two classes. An obvious interpretation is a split into formal and informal teaching styles.

Number of Clusters

We have so far studiously avoided the issue of choosing the number of clusters by assuming that an investigator is interested in the whole sequence of nested partitions or that the number of clusters is known *a priori*. However, in practice, one is often forced to decide the number of clusters from the information at hand.

A number of *ad hoc* procedures have been proposed. In the context of hierarchical clustering, selecting a partition is equivalent to cutting the corresponding dendrogram at a given height. This defines a partition such that clusters below that height are distant from each other by at least that amount. The appearance of the dendrogram can therefore informally suggest the number of clusters with large distances between fusion levels, suggesting the “best cut.” For example, applying this rule to the dendrogram in **Figure 2(c)** might suggest five clusters. In the context of optimization, clustering scree plots, which plot the values of the optimized cluster criterion against the number of groups, are most popular. By definition, the criterion improves when the number of groups is increased – so the optimal number of groups is chosen as the level at which large changes in the criterion occur (the elbow in the plot). **Figure 5** shows the scree plot for *k*-means clustering of the college data; confirming that a partition into three clusters was appropriate.

More formal techniques exist which try to overcome the problem of subjectivity. Thirty such methods were reviewed by Milligan and Cooper (1985) in the 1980s and, more recently, 15 indices for high-dimensional binary data were assessed by Dimitriadou *et al.* (2002). Both studies assess the ability of formal/automated methods to detect the correct number of clusters in series of simulated data sets. Based on these simulations techniques introduced by Calinski and Harabasz (1974) and Duda and Hart (1973) are recommended for continuous data, while the index suggested by Ratkowsky and Lance (1978) was the overall best performer for binary data.

More recently, progress on defining formal rules for comparing the quality of different cluster solutions has been made in the context of model-based clustering. As, in this context, cluster memberships are determined by optimizing likelihoods of competing nested models; the latter can be compared to inform the choice of the number of groups. There are problems with the conventional likelihood ratio test as some parameters from the null distribution are on the edge of the parameter space. However, suggestions have been made to overcome this, with perhaps the most practical one being the use of information criteria such as the Bayesian information criterion (BIC) or Akaike’s information criterion (AIC) (Burnham and Anderson, 2002). As an example, we calculated BIC for a number of models for the college data which differed in the numbers of clusters (from 1 to 5) and in the parametrization of the

Table 8 Estimated probabilities (in %) of responding yes to items for two classes of teachers

		Class 1	Class 2
1	Students have choice in where to sit	22	43
2	Students sit in groups of three or more	60	87
3	Students allocated to sitting by ability	35	23
4	Students stay in same seats for most of day	91	63
5	Students not allowed freedom of movement in classroom	97	54
6	Students not allowed to talk freely	89	48
7	Students expect to ask permission to leave room	97	76
8	Students expected to be quiet	82	42
9	Monitors appointed for special jobs	85	67

	Percentage of teachers attributed to class	54	46

covariance matrix. The latter were chosen to reflect different constraints displaying natural geometric features which can be derived from its spectral decomposition. Clusters exhibiting similar orientation, shape, or volume, satisfying two or all these restrictions, may be desirable within a particular classification context (Bensmail *et al.*, 1997). A range of these restrictions and their results for model-based selection are displayed in Figure 6: for instance, EVI

**Figure 5** Scree plot for *k*-means clustering of colleges' data.

Distributional shape implied by covariance matrix parameterization (see Fraley and Raftery, 2003)

EII: spherical, equal volume
 EVI: diagonal, equal volume, varying shape
 VII: spherical, unequal volume
 EEE: ellipsoidal, equal volume, shape, and orientation
 EEI: diagonal, equal volume and shape
 VEV: ellipsoidal, equal shape
 VEI: diagonal, varying volume, equal shape
 VVI: diagonal, varying volume and shape

Figure 6 Model selection by maximizing BIC. The best model is EEE with four clusters.

indicates that the clusters are constrained to having the same diagonal orientation and equal volume with their shape allowed to vary. Other symbols in **Figure 6** have analogous interpretations. The results show that the EEE criterion (which assumes the same covariance matrix and is equivalent to requiring similar orientation, volume, and shape for all clusters) performs well with three or four clusters.

Finally, it needs to be emphasized that a clustering algorithm will allocate objects into a prescribed number of groups, irrespective of whether there is any true clustering in the data. Many *ad hoc* methods for comparing the number of groups do not allow the consideration of the simplest clustering solution – the one-group solution. However, when empirically determining the number of clusters it is essential that the one-group solution be considered. Rules derived from maximum likelihood theory will allow this. An alternative approach is the GAP statistic (Tibshirani *et al.*, 2001), which compares the quality of cluster solutions for different numbers of groups based on a given (heuristic) cluster criterion.

Conclusion

The general steps involved in a cluster analysis are:

1. definition of the data matrix (including choice, weighting, or standardization of variables);
2. calculation of the proximity matrix;
3. choice of cluster method (to generate a single or a sequence of partitions);
4. decision regarding the number of clusters (for partitions); and
5. validity checks.

We have talked about steps 1–4 in previous sections but not much has yet been said about the final stage – checking the validity of a cluster solution. There are basically two approaches: internal checks and external checks. Internal checks are aimed at establishing cluster isolation and cohesion or demonstrating robustness of the solution under small changes of method (change of proximity measure, optimization criterion, starting values, etc.) or data set used (splitting data into subsamples, adding an error term, etc.). External checks attempt to establish agreement with a gold standard (if one exists) or with some other yet-unused variable/classification that one would theoretically expect to be associated with the solution. For more information on methods for validation checking see Everitt *et al.* (2001).

There are a number of related techniques not yet mentioned. Constrained clustering imposes restrictions on the possible cluster solutions in order to maintain external features; for example, spatial contiguity. Many applications, particularly in psychology and the social sciences, require overlapping clusters; that is, an object is

allowed to be a member of more than one cluster at the same time – for example, a member of several overlapping social networks. Under some circumstances, direct data clustering, which aims to cluster the (two-mode) data matrix into sets of similar objects and variables, can be applied. Finally, neural network techniques, such as Kohonen's self-organizing map, aimed at unsupervised learning can be considered a cluster method.

Nowadays, carrying out cluster analyses is relatively straightforward. Most general-purpose statistical packages contain procedures for hierarchical and optimization clustering. (The analyses presented here were generated in Stata and R.) Routines for model-based clustering are available in some general-purpose packages (e.g., *mclust* in R, Fraley and Raftery, 2003), specialized latent classes and finite mixtures programs (e.g., *LatentGOLD* and *MIXMOD*), or modeling packages such as *Mplus*. In addition, there are a number of packages solely devoted to cluster analyses (e.g., *Clustan*).

In summary, clustering a set of objects can potentially be very useful. However, care needs to be taken to avoid producing misleading results. Researchers do well to remember that cluster analysis is an exploratory technique rather than an inferential method.

Glossary

Abstract reasoning ability – The ability to analyze information and solve problems on complex concepts, which is also considered to be the ability to learn new things quickly.

Cognitive psychology – The branch of psychology that examines internal mental processes, including how people think, perceive, remember, and learn.

Item stimulus features – The item content, such as topics or variables that impact cognitive processes applied to an item.

Psychometrics – The field of study concerned with the theories, models, and statistical techniques applied to develop educational and psychological tests, which includes the measurement of achievement, abilities, attitudes, and personality traits.

Spatial ability – The ability to generate, retain, retrieve, and transform well-structured visual images.

Cognitive psychology, particularly the information-processing analysis of problem solving that began in the 1970s, has influenced important developments in psychometrics. According to Mislevy (2006: 262), the focus of the information-processing analysis in psychometrics is on what is happening within people's heads while they are responding to items. Thus, the interpretation of test performance reflects a complex combination of component processing skills, strategies, and knowledge structures (Snow and Lohman, 1993). As noted by Bejar (2008), the synergy between cognitive psychology and psychometrics also led to cognitively based item generation in the 1980s. A well-developed cognitive theory can provide a framework for item design. The cognitive theory elaborates how specific item stimulus features influence the cognitive requirements involved in responding to the item, which in turn allows the test developer to design items for specific levels and sources of cognitive complexity. These design principles may also be embedded in a computer program to automatically generate items with predictable psychometric properties. Item generators have been developed for measuring nonverbal or fluid intelligence, including matrix reasoning items (Embretson, 1998, 1999) and spatial visualization items (Embretson and Gorin, 2001). An item generator has also been developed for mathematical reasoning

items, which can produce new items while the examinee takes the computerized adaptive test (see Bejar *et al.*, 2003).

However, the impact of the cognitive psychology approach is strongest when appropriate statistical models are applied to estimate parameters that reflect the impact of the cognitive test design features on item psychometric properties. If the prediction from the cognitive model is sufficiently strong, it may be possible to use items with little or no empirical tryout (Embretson and Yang, 2007).

In this article, the test design approach for cognitively based item generation is reviewed, and some statistical models that are appropriate for calibrating item psychometric properties are presented. Finally, the test design approach and the corresponding statistical models are illustrated by applications to spatial ability and abstract reasoning.

Test Design for the Cognitively Based Item Generation

Cognitive principles can be incorporated into test design to support construct validity and to test score interpretations. In an earlier article (Embretson, 1998), it was noted that the traditional test development process associated with construct validation has limited implications for test design for two reasons. First, the traditional conceptualization of construct validity emphasizes the establishing of significant relationships of test scores with external variables, such as other measures or criteria. However, this approach confounds the theoretical meaning of the construct with its significance in prediction. Thus, the role of cognitive theory in test design is limited. Second, in the traditional test development process, the evaluation of construct validity is possible only after the test has been developed and data have been collected. If the results do not support the intended construct validity of the test, then test developers must either redefine the construct or redesign the test. Since the latter possibility requires new evidence of construct validity of the test, redefining the construct is often the more practical option. Because of these limitations, the traditional test development approach does not fully establish the theoretical nature of the constructs that are measured during test development phase.

To overcome the limitations of the traditional approach, a principled test design approach with the centralization of cognitive theory is necessary. Mislevy's

evidence-centered design (Mislevy, 1994) and Embretson's cognitive design system (CDS; Embretson, 1994, 1998) are two principled test design approaches. Although the evidence-centered design approach is very flexible and permits diverse applications, the CDS approach is more directly applicable to typical large-scale assessments because items may be banked by estimates of cognitive complexity, which can be useful in equating both linear and adaptive test forms.

The CDS framework interfaces item design principles with test validity by including both a conceptual and a procedural framework. In the conceptual framework, the construct validation concept is divided into two aspects: construct representation and nomothetic span (see Embretson, 1983, 1998). Construct representation concerns the meaning of test scores by understanding the processes, strategies, and knowledge that examinees use to solve items. Nomothetic span concerns the significance of test scores, as determined from external evidence, such as correlations of test scores with other variables. Even though nomothetic span does not define test meaning, it is the consequence of construct representation (Embretson, 1998). The two-part distinction in construct validity can be applied to establish the theoretical nature of the constructs that are measured in the test design phase.

The procedural framework is a series of stages that are shown in **Table 1**. In the first two stages, specification of general goals of measurement is followed by the identification of design features for test items. Although the traditional test development approach also has these stages, cognitive psychology has a central role in CDS because item design features that impact cognitive processing demands are identified. The next four stages in **Table 1** concern item development. This is a research process in which the cognitive modeling results are combined with the target measurement goals. Test developers select or develop cognitive models to represent the item-solving process, and then these models are evaluated empirically on test items. Once a plausible cognitive model has been obtained, the item specifications can be developed based on the variables in the model. That is, the cognitive model variables define stimulus features in the items that can be varied to produce items with specified levels and sources of cognitive complexity. In addition, item stimulus features that prompt irrelevant processes to target measurement goals can be minimized. In the remaining stages, test developers evaluate the psychometric properties of the test using statistical models of item properties. Item parameters are estimated to assess the impact (i.e., magnitude and significance) of the item stimulus features on psychometric properties (e.g., item difficulty). Significant weight parameters of the stimulus features can be interpreted as supporting the cognitive model as well as the construct representation of the test. Another advantage of the CDS approach is the possibility

Table 1 Cognitive design systems

of banking items. As item parameters can be predicted by the stimulus features in the cognitive model prior to tryout, items can be banked by their cognitive demands.

Statistical Models

The many advantages of principled test design involve statistical models to link substantive features of items to psychometric properties. Next, some models that are appropriate for CDS and other design systems are reviewed.

Linear Logistic Test Model

The linear logistic test model (LLTM; Fischer, 1973) was the first psychometric model to effectively bridge cognitive psychology and item design. That is, the model can incorporate item stimulus features into the prediction of

item success. LLTM is a generalization of the Rasch item response theory (IRT) model, which is given as

$$P(X_{is} = 1) = \frac{\exp(\theta_s - \beta_i)}{1 + \exp(\theta_s - \beta_i)}, \quad [1]$$

where $P(X_{is} = 1)$ is the probability that person s answers item i correctly, θ_s is the trait level of person s , and β_i is the difficulty parameter of item i . Because β_i does not include the cognitive variables (item stimulus features) involved in the item, it is replaced with a linear function of cognitive variables in LLTM as follows:

$$\beta_i = \sum_{k=0}^K \eta_k q_{ik} = \eta_0 q_{i0} + \eta_1 q_{i1} + \eta_2 q_{i2} + \cdots + \eta_K q_{iK}, \quad [2]$$

where η_k represents the effect of stimulus feature k , q_{ik} is the score (e.g., 0 = absence; 1 = presence) of stimulus feature k of item i , and $\eta_0 q_{i0}$ is the intercept of the equation. The full LLTM combines eqn [1] with eqn [2]:

$$P(X_{is} = 1) = \frac{\exp(\theta_s - \sum_{k=0}^K \eta_k q_{ik})}{1 + \exp(\theta_s - \sum_{k=0}^K \eta_k q_{ik})}. \quad [3]$$

The \mathbf{Q} matrix that consists of q_{ik} (the indicators of k stimulus features of i items) is usually structured as a (I, K) matrix with rank K , where $K < I$. The method of coding the indicators, q_{ik} , can be either dummy coding or scores for the item on cognitive model variables, depending on the purpose of the application. The example of spatial ability presented below will elaborate how the q_{ik} is coded to represent cognitive model variables.

Two-Parameter-Logistic-Constrained Model

The two-parameter-logistic(2PL)-constrained model (Embretson, 1999) contains parameters to represent the impact of stimulus features on item discrimination as well as on item difficulty. It was first presented with an application to matrix completion items in which item difficulty and item discrimination were both predictable from item stimulus features (Embretson, 1999). Analogous to LLTM, which is a generalization of the Rasch IRT model, the 2PL-constrained model is a generalization of the 2PL model. In the 2PL-constrained model, both item discrimination (α_i) and item difficulty (β_i) parameters of the 2PL model are replaced with the linear combinations of cognitive variables as follows:

2PL model :

$$P(X_{is} = 1) = \frac{\exp[\alpha_i(\theta_s - \beta_i)]}{1 + \exp[\alpha_i(\theta_s - \beta_i)]}; \quad [4]$$

$$\alpha_i = \sum_{k=0}^K \tau_k q_{ik}, \beta_i = \sum_{k=0}^K \eta_k q_{ik}; \quad [5]$$

2PL-constrained model:

$$P(X_{is} = 1) = \frac{\exp[\sum_{k=0}^K \tau_k q_{ik}(\theta_s - \sum_{k=0}^K \eta_k q_{ik})]}{1 + \exp[\sum_{k=0}^K \tau_k q_{ik}(\theta_s - \sum_{k=0}^K \eta_k q_{ik})]}, \quad [6]$$

where $P(X_{is} = 1)$ is the probability that person s passes item i , θ_s is the ability of person s , q_{ik} is the score for stimulus feature k in item i , τ_k and η_k are the weights (or effects) of stimulus feature k in item discrimination and item difficulty, respectively, and $\tau_0 q_{i0}$ and $\eta_0 q_{i0}$ are the intercepts of the equations.

The advantage of the 2PL-constrained model over LLTM is that it includes design features for item discrimination. An item with higher discriminating power provides more information about latent trait (θ) along with less measurement error because the changes in trait level have a greater impact on $P(X_{is} = 1)$ of that item. If we use the 2PL-constrained model, we can identify which item stimulus features affect the discriminating power of the item as well as item difficulty. The application of the 2PL-constrained model is introduced in the example of abstract reasoning ability test below.

Linear Partial Credit Model

The linear partial credit model (LPCM; Fischer and Ponocny, 1994) was developed to assess the effects of treatments based on polytomous ordered response items. Like the LLTM, the LPCM includes the linear function of cognitive variables involved in the item. However, unlike the LLTM that is applicable only to binary response data (e.g., right or wrong), it is designed for analyzing polytomous ordered responses, which are commonly used for attitude or self-rating items. The LPCM is based on the partial credit model, which assigns one independent parameter β_{ib} for each response category of an item as follows:

$$P(X_{ibs} = 1) = \frac{\exp(b\theta_s + \beta_{ib})}{\sum_{b=0}^{H_i} \exp(b\theta_s + \beta_{ib})}, \quad [7]$$

for $i = 1, \dots, I$ items and $b = 0, \dots, H_i$ response categories of item i , where $P(X_{ibs} = 1)$ is the probability that person s chooses category b on item i (all X_{ibs} are assumed to be locally independent), θ_s is the position of person s on the underlying latent trait, and β_{ib} is the easiness parameter of category b of item i (β_{i0} and $\sum_{i=1}^I \sum_{b=1}^{H_i} \beta_{ib}$ are set to zero for model identification and normalization).

In the LPCM, β_{ib} is replaced with a linear function of cognitive variables

$$\beta_{ib} = \sum_{k=0}^K \alpha_k w_{ibk}, \quad [8]$$

where α_k is called the basic parameter, which measures the effect of stimulus feature or experimental treatment k on the response in item i , w_{ibk} is the value of the stimulus

feature or dosage of the treatment, and $\alpha_0 w_{ib0}$ is a normalization constant of the equation. Notice that α_k and w_{ibk} in the LPCM correspond to η_k and q_{ik} in the LLTM (see eqn [2]), respectively. The combination of eqn [7] with eqn [8] is the LPCM.

$$P(X_{ibs} = 1) = \frac{\exp(b\theta_s + \sum_{k=0}^k \alpha_k w_{ibk})}{\sum_{b=0}^{H_i} \exp(b\theta_s + \sum_{k=0}^k \alpha_k w_{ibk})} \quad [9]$$

One of the attractive features of the LPCM is its great flexibility in allowing the w_{ibk} parameter for each response category, thus resulting in a good fit to complex data. However, it should be noted that there is always a trade-off between the flexibility and the simplicity (ease of interpretation) of a model.

Multicomponent Latent Trait Model

Many ability and achievement tests have sources of multidimensionality in the item domain. For example, the Scholastic Aptitude Test (SAT) algebra items require multiple skills or stages to arrive at a correct response, such as prerequisite skills for symbols and conventions, algebraic manipulations, linear functions, and simultaneous equations (Gierl *et al.*, 2007). To better explain why an examinee answers a specific item incorrectly, statistical models that can assess the sources of multidimensionality are needed.

One important aspect of multidimensionality is that the skills or processing stages in the items are often sequentially dependent. Thus, cognitive models for tasks typically postulate a flow of information from one stage to another. Four possible forms of hierarchical structures of processing stages in task performance are presented

Figure 1 Four different hierarchical structures. Reproduced from Gierl, M. J., Leighton, J. P., and Hunka, S. M. (2007). Using the attribute hierarchy method to make diagnostic inferences about examinees' cognitive skills. In Leighton, J. P. and Gierl, M. J. (eds.) *Cognitive Diagnostic Assessment for Education*, pp 242–274. New York: Cambridge University Press.

in **Figure 1** (Gierl *et al.*, 2007). In all the structures, there is a prerequisite skill (stage 1) and orderings among all or some processing stages except in **Figure 1(d)**, which is an unstructured hierarchy.

The multidimensional latent trait model (MLTM; Whitely, 1980) was designed to properly reflect the sequentially dependent stages (called components in this model) based on a product of processing outcome probabilities as follows:

$$P(X_{is} = 1) = \prod_k P(X_{isk}) = \prod_k \frac{\exp(\theta_{sk} - \beta_{ik})}{1 + \exp(\theta_{sk} - \beta_{ik})}, \quad [10]$$

where $P(X_{is} = 1)$ is the probability of success for person s on item i and $\prod_k P(X_{isk})$ is the product of success on each processing component k , given the correct outcome of the preceding component. The right side of the equation contains terms from the Rasch models for the probability of success on each component, where θ_{sk} is the trait level of person s on component k and β_{ik} is the difficulty of item i on component k .

General Component Latent Trait Model

The general component latent trait model (GLTM; Embretson, 1984) is the generalization of the MLTM, which incorporates component stimulus features into the prediction of the component difficulty (β_{ik}) in the item. Therefore, β_{ik} in Equation 10, is replaced with the weighted sum of underlying stimulus features as follows:

$$\beta_{ik} = \sum_{m=0}^m \eta_{km} q_{ikm}, \quad [11]$$

where q_{ikm} is an indicator of the presence (or polynomial values) of stimulus feature m on component k for item i , η_{ikm} is the weight of stimulus feature m on component k , and $\eta_{k0} q_{ik0}$ is an intercept. The full GLTM combines eqn [10] with eqn [11].

$$P(X_{isT} = 1) = \prod_k \left[\frac{\exp(\theta_{sk} - \sum_{m=0}^m \eta_{km} q_{ikm})}{1 + \exp(\theta_{sk} - \sum_{m=0}^m \eta_{km} q_{ikm})} \right]. \quad [12]$$

Like MLTM, GLTM can be estimated readily when both subtask and full task data are available for the same item. The GLTM can be estimated with full task data only under certain circumstances. For example, in Embretson's (1995) study, a working-memory capacity component was separated from the control processes in performance on spatial ability items because a highly predictive model for the difficulty of working memory load was available. Other circumstances in which GLTM can be estimated include setting constraints, data augmentation, and component structures that vary between items.

The GLTM enables us to examine how the underlying stimulus features will impact the difficulty of each component (β_{ik}) based on preestablished cognitive theories. Since GLTM is an extension of the MLTM, it also

estimates individual ability on each component, thus giving more detailed information about an examinee's skill profile.

Applications

Two examples are presented below to illustrate the application of the statistical models to item design. Both examples involve nonverbal measures of ability. Applications of LLTM and the 2PL-Constrained model to items that appear on achievement tests, such as paragraph comprehension (Gorin, 2005) and mathematical problem solving (Embretson and Daniel, 2008), are also available.

Spatial Ability

Embretson (1994) developed the spatial learning ability test (SLAT) by applying the CDS approach. In her study, the practical efficiency of the CDS and the constructive representation of the SLAT were strongly supported. Based on a series of research and cognitive models of the spatial folding task, Embretson (1994) found that the degrees of rotation and the number of surfaces carried provided a good prediction of both item difficulty and response time (see **Figure 2**).

Figure 2 provides some examples to show what the degree of rotation means and what the number of surfaces carried implies in the SLAT item. This figure consists of an unfolded stem on the left side and six cubes (or keys) on the right side, which possibly result from folding down the unfolded stem. The six different keys vary in the degrees of rotation and in the number of surfaces carried. For example,

Figure 2 A stem and six correct answers that vary in the degrees of rotation and the surfaces carried. Reproduced from Embretson, S. E. (1994). Application of cognitive design systems to test development. In Reynolds, C. R. (ed.) *Cognitive Assessment: A Multidisciplinary Perspective*, pp 107–135. New York: Plenum Press.

the three keys in the top row of **Figure 2** require different degrees of mental rotation of the unfolded stem to match the stem with the keys 0° , 90° , and 180° , respectively. However, the three keys in the bottom row have 0° of rotation but vary in the number of surfaces required to be carried in folding processes. That is, in the first key of the three, all the three surfaces of \uparrow , \blacksquare , and \blacksquare are adjacent; thus the number of surfaces required to be carried in the mental folding processes is counted as one. In the second key, the surfaces of \uparrow and of \blacksquare are not adjacent; they are two surfaces apart from each other, thus requiring more complex mentally folding process than in the first key. The maximum number of surfaces required to be carried in the mental folding processes is counted as two in this case. Likewise, the maximum number of surfaces required to be carried in the third key is three because the surfaces of \uparrow and of \blacksquare are three surfaces apart from each other. These two sources of cognitive complexity (the degrees of rotation and the number of surfaces carried) were found to have a linear relationship to item difficulty and item response time, thus supporting the theory that mental rotation is analogous to physical rotation (Embretson, 1994).

Distractor types may also impact the folding process (Embretson, 1994). **Figure 3** presents two sample SLAT items. The task is to select one of the four distractors that best matches the unfolded stem on the left side. For the top item of **Figure 3**, each distractor has the same markings (called matched positions), whereas all distractors of the bottom item show different markings (called mixed positions). Mixed positions in the distractors seem to cause greater response time and less accuracy (Embretson, 1994). In the distractors of the top item, the two surfaces of \uparrow and \square are called anchoring points because they are pairs of surfaces with the same markings between the unfolded stem and a distractor. A search process for anchoring points is a prerequisite to the rotation and the folding process in order to solve a SLAT item. Finally, the item on the bottom of **Figure 3** contains two surfaces with undirected markings (i.e., \blacksquare and \square). These two markings

Figure 3 Two SLAT items. From Embretson, S. E. (1994). Application of cognitive design systems to test development. In Reynolds, C. R. (ed.) *Cognitive Assessment: A Multidisciplinary Perspective*, pp 107–135. New York: Plenum Press.

(called undirected markings) appear the same in every orientation, unlike all other markings such as \square and \blacksquare (called directed markings). An item containing undirected markings does not require folding processes and is called a position problem, whereas an item with only directed markings is called a spatial problem. The position problem will be easier than the spatial problem because there is no involvement of the folding process (Embretson, 1994).

In the research on SLAT, eight cognitive variables (stimulus features) were scored in the LLTM based on the cognitive models of the spatial folding task, elaborated above: (1) distractor type, (2) problem type, (3) degrees rotation-linear, (4) degrees rotation-quadratic, (5) surfaces carried-linear, (6) surfaces carried-quadratic, (7) degrees rotation-linear (position items), and (8) degrees rotation-quadratic (position items). **Table 2** shows details on coding each stimulus feature (q_{ik}).

Distractor type and problem type variables are coded by binary numbers (0 and 1). The degrees of rotation and the number of surfaces carried ($q_3, q_4, q_5, q_6, q_7, q_8$) are coded by polytomous numbers to test for both linear and

quadratic trends. For example, if the item has a 90° rotation, the values for the linear contrast and for the quadratic contrast (i.e., q_3 and q_4) will be 0 and -2 , respectively (see **Table 2**). It should be noted that q_3, q_4, q_5 , and q_6 are coded only for spatial items (otherwise, coded as 0), while q_7 and q_8 are scored for position items only (otherwise, coded as 0). Therefore, the degrees of rotation of spatial and position problems are scored separately. For example, if a spatial item has a mixed orientation of distractors, a 180° rotation, and two surfaces carried, then item difficulty (β_i) would be predicted as follows (refer to eqn [2]):

$$\hat{\beta}_i = \eta_0 q_0 + \eta_1(1) + \eta_2(0) + \eta_3(1) + \eta_4(1) + \eta_5(0) + \eta_6(-2) + \eta_7(0) + \eta_8(0).$$

Embretson (1994) also extended mathematical modeling with the cognitive variables to model item response time. The effect parameter (η) of each cognitive variable (q_k) on item difficulty was estimated with LLTM, while the regression coefficient (b) of q_k on item response time was estimated with regression analysis. **Table 3** provides the estimates of the parameters for item difficulty and response time. As shown in **Table 3**, degrees of rotation and the number of surfaces carried contrasts have a significant impact on both item difficulty and item response time in the SLAT. Problem type (spatial vs. position) has a strong impact on item difficulty but not on response time. However, distractor type (matched vs. mixed) is not significant for either item difficulty or item response time.

Abstract Reasoning Ability

The Abstract Reasoning Test (ART; Embretson, 1995) was developed based on the Carpenter *et al.* (1990) processing theory of matrix completion tasks. In the Carpenter *et al.* theory, the major processes involved in solving the matrix completion problems are the generating and evaluating of relationships across the rows and columns. Based on results

Table 2 Cognitive variables and the coding in LLTM

q_k	Cognitive variables	Coding
q_1	Distractor type	0 = matched, 1 = mixed
q_2	Problem type	0 = spatial, 1 = position
q_3	Degrees rotation-linear	$-1 = 0^\circ, 0 = 90^\circ, 1 = 180^\circ$
q_4	Degrees rotation-quadratic	$1 = 0^\circ, -2 = 90^\circ, 1 = 180^\circ$
q_5	Surfaces carried-linear	$-1 = 1 \text{ surface}, 0 = 2 \text{ surfaces}, 1 = 3 \text{ surfaces}$
q_6	Surfaces carried-quadratic	$1 = 1 \text{ surface}, -2 = 2 \text{ surfaces}, 1 = 3 \text{ surfaces}$
q_7	Degrees rotation linear position-items	$-1 = 0^\circ, 0 = 90^\circ, 1 = 180^\circ$
q_8	Degrees rotation quadratic position-items	$1 = 0^\circ, -2 = 90^\circ, 1 = 180^\circ$

Table 3 Cognitive models of item difficulty and response time

Cognitive variable	Item difficulty		Response time	
	η	σ_η	b	σ_b
1. Distractor type	-0.07	0.04	0.78	0.48
2. Problem type	-0.10**	0.05	-0.16	0.55
3. Degrees rotation-linear	0.16**	0.03	1.76**	0.34
4. Degrees rotation-quadratic	0.10**	0.02	0.48*	0.20
5. Surfaces carried-linear	0.83**	0.03	3.65**	0.34
6. Surfaces carried-quadratic	-0.18**	0.02	-1.09**	0.20
7. Degrees rotation linear position-items	-0.01	0.05	-0.07	0.58

from a variety of experiments, it was postulated that working-memory capacity was a primary source of individual differences in item solving (Carpenter *et al.*, 1990).

The working-memory load in a matrix problem is influenced by both the number and the level of relationships involved across the rows and columns. First, for the number of relationships of the ART item in **Figure 4**, there is a distribution of three objects (\square , \circ , and Δ), which occur once and only once in each row and column. Moreover, there are two pairwise progressions, that is, the interior object (\times) changes its girth across the columns and its density across the rows. Therefore, a total of three relationships (one distribution of three + two pairwise progressions) are involved in the item in **Figure 4**. Second, for the level of relationships, Carpenter *et al.* (1990) identified five levels, as shown in **Table 4**.

It was observed that people examined one relationship at a time from level one to the higher levels in **Table 4** until they reached the required relationship to solve the matrix item (Carpenter *et al.*, 1990). Thus, they hypothesized that the higher-level relationship requires more processing time as well as extra working-memory capacity to remember the results of earlier processing than the lower-level relationship does. Therefore, greater numbers

Figure 4 A sample item of the ART. Adapted from Embretson, S. E. (2002). Generating abstract reasoning items with cognitive theory. In Irvine, S. and Kyllonen, P. (eds.) *Generating Items for Cognitive Tests: Theory and Practice*, pp 219–250. Mahwah, NJ: Erlbaum.

Table 4 Order of relationships to apply for matrix problems

Level	Relationship	Definition
1	Constant in a row	An element is the same across rows or columns
2	Pairwise progression	An element changes systematically from entry to entry
3	Figure addition/subtraction	The first two entries in the row or column visually sum to the last entry
4	Distribution of three	An object or attribute appears just once in each row and column
5	Distribution of two	Distribution of three has null values (i.e., one matching element is missing)

and levels of relationships require more working-memory capacity in an examinee. The item in **Figure 4** has two pairwise progressions (level 2, in **Table 4**) and a distribution of three (level 4, in **Table 4**) as we already know. Therefore, the number of the relationships involved in this ART item in **Figure 4** is three, and the levels of the relationships involved in the item are 2 and 4.

Carpenter *et al.* (1990) proposed an additional source of individual difference in solving matrix problems, namely, abstraction capacity. Abstraction capacity is involved in finding abstract correspondence between figures, especially when (1) the correspondence is based on the properties of objects (e.g., position in the entry, texture, orientation), (2) corresponding objects are distorted, or (3) the relationship involves null values. Null values are characteristic of the distribution of two relationships (level 5, in **Table 4**). For example, the sample item in **Figure 5** has a distribution of two objects (\square , Δ) across the rows and columns, while the third object is null. In addition, a figure addition/subtraction relationship (level 3 in **Table 4**) can be found among the interior objects (e.g., $++$, $++$, and $+$). Null values are applicable to the addition/subtraction relationship, if the results of subtractions are zeros.

Carpenter *et al.* (1990) did not introduce any mathematical modeling to predict item difficulty by the sources of individual difference (i.e., working-memory load or abstract correspondence). Embretson (1998) developed ART based on the cognitive variables of Carpenter *et al.* (1990) using the CDS approach. Further, the predictability of item performance from the cognitive model variables was also studied using one of the statistical models described above. To generate items in the CDS approach, the cognitive variables should first be scored in an appropriate statistical model as in the previous example of the SLAT. Embretson (1998) added three perceptual variables to examine if the drawing principles for the item influence item difficulty, in addition to the two cognitive variables (i.e., number of relationships and abstract correspondence). Embretson's perceptual variables are overlay, fusion, and distortion: (1) overlay is scored 1 if independent objects (e.g., \square or \times) are overlaid in an array entry as in **Figure 4**, and 0 if they are placed side by side in the same array location; (2) fusion is scored 1 if two objects placed side by side appear as one object, and 0 otherwise; and (3) distortion is scored 1 if the shape of corresponding objects change perceptually (bending, twisting, stretching, etc.), and 0 otherwise. The 2PL-constrained model was applied because preliminary analyses revealed somewhat unequal item discriminations in the ART. **Table 5** presents two cognitive variables (q_1 , q_2) and three perceptual variables (q_3 , q_4 , and q_5) in the ART and specifies the codes of the sample item of **Figure 4**.

Embretson (1999) estimated the weights (τ_k , η_k) of the stimulus features using a sample of 818 young adults with

Figure 5 A sample ART item with null values. Adapted from Embretson, S. E. (1998). A cognitive design system approach to generating valid tests: Application to abstract reasoning. *Psychological Methods* 3, 300–396.

Table 5 Cognitive/perceptual variables in the ART and the codes for the sample item in Figure 4

q_k	Cognitive/perceptual variables	Codes for the sample item
q_1	Number of relationships	3 (One distribution of three + 2 pairwise progressions)
q_2	Abstract correspondence	0 (no abstract correspondence)
q_3	Overlay	1 (overlaid)
q_4	Fusion	0 (no fusion)
q_5	Distortion	0 (no distortion)

Table 6 Estimates for 2PL-constrained model

Item stimulus feature	Item discrimination		Item difficulty	
	τ	σ_τ	η	σ_η
Intercept	1.710**	0.071	–1.421**	0.069
1. Number of relationships	–0.327**	0.021	0.514**	0.022
2. Abstract correspondence	0.056	0.037	0.844**	0.041
3. Overlay	–0.067	0.038	0.245**	0.039
4. Fusion	–0.107*	0.052	–3.08**	0.047
5. Distortion	0.237**	0.054	–0.064	0.056

* $p < 0.05$; ** $p < 0.01$.

30 item forms of the ART. Table 6 provides the estimated weights for item discrimination and item difficulty and their standard errors. The number of relationships had a significant effect for both item discrimination and item difficulty at the 0.01 level. The number of relationships was negatively associated with item discrimination and positively associated with item difficulty. That is, an item with more relationships across the rows and columns was more difficult but had less discriminating power. Abstract correspondence showed a strong impact on item difficulty but not on item discrimination. For the perceptual features,

fusion showed significant impact on both item discrimination and on item difficulty at the 0.05 level. Therefore, the item discrimination (α_i) and item difficulty (β_i) of the sample item in Figure 4 can be predicted using the 2PL-constrained model as follows:

$$\hat{\alpha}_i = \sum_{k=0}^K \tau_k q_{ik} = 1.710 - 0.327(3) + 0.056(0) - 0.067(1) - 0.107(0) + 0.237(0) = 0.662;$$

$$\hat{\beta}_i = \sum_{k=0}^K \eta_k q_{ik} = -1.421 + 0.514(3) + 0.844(0) + 0.245(1) - 3.08(0) - 0.064(0) = 0.366.$$

Summary

Cognitive psychology has greatly improved the understanding of skills and knowledge structures in task performance. The cognitive theories may also be applied to the development of educational and psychological testing when items have been studied as cognitive tasks. In this article, a principled test design approach, the CDS, and some statistical models that are appropriate to incorporate cognitive theories into the test design system were reviewed. In addition, examples of applications to two different tests were elaborated to show how cognitive variables can be scored on preexisting cognitive theories and how appropriate statistical models can be applied to estimate the effect of the cognitive variable on item parameters. Mathematical modeling with well-supported cognitive theories makes it possible to predict item psychometric properties with little or no empirical tryout, thus bringing the interesting possibility of automatic item generation during the test.

Computational Statistics

J E Gentle, George Mason University, Fairfax, VA, USA

Introduction

Statistical data analysis has always involved computations, and statisticians have traditionally been heavy consumers of CPU cycles. Grier (1999) describes the concurrent development of data analysis, computing machinery, and statistical computing. The development of the personal computer and of user-friendly software for statistical applications has changed many aspects of a statistician's work, but one thing that has not changed is the pressure to develop methods to utilize advanced computing facilities in statistical analyses.

Although all data analysis involves computation, we do not identify all data analysis as 'statistical computing' or as 'computational statistics'. These terms do not refer to straightforward use of a statistical software package to do a standard analysis. We use the term 'statistical computing' to refer to the computational methods that enable statistical methods. The field of statistical computing is grounded in numerical analysis, database methodology, computer graphics, software engineering, and the computer/human interface. The results of research and development in the area of statistical computing have been incorporated in software packages, and for straightforward problems, very little knowledge of this field is necessary for the applied statistician who merely needs access to the software package. To build software to implement a new statistical method, however, the research statistician or software engineer needs a strong background in statistical computing.

We use the term 'computational statistics' somewhat more broadly to include not only the methods of statistical computing, but also a large class of modern statistical methods that are computationally intensive. The field of computational statistics is grounded in mathematical statistics, statistical computing, and applied statistics. The methods of computational statistics would not be possible without the developments in statistical computing.

Emergence of Computational Statistics as a Subdiscipline

Most of the early leaders in the development of both theoretical and applied statistics, such as Fisher and the Pearsons, were masters of the computational machinery of their day. As the machinery became more advanced in the middle third of the twentieth century, some of the computational aspects of the work were passed off to technicians or else was performed by statisticians who did not understand

the nature of numerical computations on the newer hardware. The numerical computations in many statistical analyses were not of high quality; consequently, the analyses often lacked validity. In the face of a growing realization of the numerical inaccuracies, especially for larger and more ill-conditioned problems, there was a spate of activity by both numerical analysts and statisticians with strong backgrounds in numerical mathematics to advance the quality of algorithms and software for statistical computing.

A Working Party on Statistical Computing was formed within the Royal Statistical Society in the late 1960s, the Statistical Computing Section of the American Statistical Association was formed in 1971, and the International Association for Statistical Computing was founded in 1977 as a Section of the International Statistical Institute. All of these associations remain active today in promoting research in statistical computing. Beginning in 1967, the *Symposium on the Interface of Computer Science and Statistics* has been held annually (with only a few exceptions). The biennial COMPSTAT conferences on computational statistics began in 1974. These scholarly associations and conferences promoted research in statistical computing and contributed greatly to the development of the field.

Another important facet of the development of computational statistics has been the large number of peer-reviewed journals devoted to the field. The journals in the mainstream of statistics also have a large proportion of articles in the fields of statistical computing and computational statistics. This is because, to a large extent, recent developments in statistics and in the computational sciences have gone hand in hand.

Some of the major journals in statistical computing and computational statistics are the following.

- *Communications in Statistics – Simulation and Computation*, published quarterly by Marcel Dekker. (Until 1996, it included algorithms in Fortran. Until 1982, this journal was designated as *Series B*.)
- *Computational Statistics* published quarterly by Physica-Verlag (formerly called *Computational Statistics Quarterly*).
- *Computational Statistics. Proceedings of the xxth Symposium on Computational Statistics (COMPSTAT)*, published biennially by Physica-Verlag. (It is not refereed.)
- *Computational Statistics & Data Analysis*, published by North-Holland. The number of issues per year varies. (This is also the official journal of the International Association for Statistical Computing and as such incorporates the *Statistical Software Newsletter*.)

- *Computing Science and Statistics*. This is an annual publication containing papers presented at the Interface Symposium. Publication began in 1967 under the title *Computer Science and Statistics: Proceedings of the xxtb Symposium on the Interface*. Since 1992, the shorter name has been used. It is published by the Interface Foundation of North America. (It is not refereed.)
- *Journal of Computational and Graphical Statistics*, published quarterly by the American Statistical Association.
- *Journal of the Japanese Society of Computational Statistics*, published once a year by the Japanese Society of Computational Statistics.
- *Journal of Statistical Computation and Simulation*, published irregularly in four numbers per volume by Gordon and Breach.
- *Proceedings of the Statistical Computing Section*, published annually by the American Statistical Association. (It is not refereed.)
- *Statistical Computing and Graphics Newsletter*, published quarterly by the Statistical Computing and the Statistical Graphics Sections of the American Statistical Association. (It is not refereed and it is not generally available in libraries.)
- *Statistics and Computing*, published quarterly by Chapman and Hall.

Education in Computational Statistics

Beginning in the late 1960s and early 1970s, most major academic programs in statistics offered one or more courses in statistical computing. The educational programs have promoted the identity of computational statistics as an academic discipline. Instruction in computational techniques has also permeated many of the standard courses in applied statistics.

Developments in computing and the changing role of computations in statistical work have had significant effects on the curricula of statistical education programs both at the graduate and undergraduate levels. Training in statistical computing is a major component in some academic programs in statistics (see Gentle, 2004; Lange, 2004; Monahan, 2004). In all academic programs, some amount of computing instruction is necessary if the student is expected to work as a statistician. The extent and the manner of integration of computing into an academic statistics program, of course, change with the developments in computing hardware and software and in computational statistics.

Numerical Analysis for Statistical Applications: Statistical Computing

The most obvious use of the computer is in support of the existing statistical methods. This does not just involve

some simple computer programming. While anyone can write a program to solve a well-conditioned system of linear equations, to write a robust program that can handle large-scale and ill-conditioned systems efficiently and to implement a smooth user interface, require a considerable amount of training in numerical analysis, as well as an intimate knowledge of the computer hardware and the programming language.

There are some general principles of computer arithmetic that pervade all types of computations. There are also general aspects of all numerical algorithms, but a good algorithm for a specific type of computation may involve some very special steps. An overview of the area of statistical computing is given in part II of the handbook edited by Gentle *et al.* (2004), which includes articles such as ‘random number generation’, ‘Markov chain Monte Carlo technology’, ‘numerical linear algebra’, ‘the grammar of graphics’, ‘object oriented computing’, and so on. Some of these topics are relevant to anyone developing numerical software, some topics are relevant to the careful user of statistical software, and some are important to the developer of software packages.

Three important areas of statistical computing are random number generation, numerical linear algebra, and optimization.

Computations to Support Simulation Methods

The role of Monte Carlo methods and simulation in all of the sciences has increased in importance during the past several years. The growing power of computers and the evolving simulation methodology have led to the recognition of computation as a third approach for advancing the natural sciences, together with theory and traditional experimentation. Monte Carlo is also a fundamental tool of computational statistics. At the kernel of a Monte Carlo or simulation method is random number generation.

Generation of random numbers is also at the heart of many standard statistical methods. The random sampling required in most analyses is usually done by the computer.

The computations required in Bayesian analysis have become viable because of Monte Carlo methods. This has led to much wider applications of Bayesian statistics, which, in turn, has led to the development of new Monte Carlo methods and to the refinement of existing procedures for random number generation.

Various methods for the generation of random numbers have been used. Sometimes, processes that are considered random, are used, but for Monte Carlo methods, which depend on millions of random numbers, a physical process as a source of random numbers is generally cumbersome. Instead of random numbers, most applications

use pseudorandom numbers, which are deterministic but look like they were generated randomly. While many of the earlier random number generators yielded sequences with obvious nonrandom patterns, there are now a number of reliable methods for the generation of sequences of pseudorandom numbers that simulate a uniform distribution over the unit interval (see Gentle, 2003). These are the basic sequences from which are derived pseudorandom numbers from other distributions, pseudorandom samples, and pseudostochastic processes.

Numerical Linear Algebra

Linear algebra is one of the most important mathematical and computational tools in the sciences. One of the most important tools in data analysis is the linear regression model. The main computations required for an analysis using this model are to solve an overdetermined system of linear equations, usually so as to minimize the sum of squares of the deviations. The simplest way these computations can be performed under the least-squares criterion is by first forming the normal equations and then solving them. This method is neither computationally efficient nor numerically stable. Some of the most important early work in statistical computing was the development of good algorithms to solve this problem. These algorithms begin decomposition of the matrix of values of the covariates (see Čížková and Čížek, 2004).

While linear models and linear transformations are important in their own right, the basic role that linear algebra plays in nonlinear models, in optimization, and in other areas of statistics, also makes an understanding of linear methods one of the most fundamental requirements for research in statistics or in the application of statistical methods.

Numerical Solution of Optimization Problems

Optimization problems – maximization or minimization – arise in many areas of statistics. Statistical estimation and modeling both are usually special types of optimization problems. In a common method of statistical estimation, we maximize a likelihood, which is a function proportional to a probability density at the point of the observed data. In another method of estimation and in standard modeling techniques, we minimize a norm of the residuals. The best fit of a model is often defined in terms of a minimum of a norm, such as least squares. The other uses of optimization in statistical applications occur prior to the collection of data, for example, when we design an experiment or a survey so as to minimize experimental or sampling errors.

When a statistical method is based on the solution of an optimization problem, to formulate that problem

unambiguously helps us both to understand the method and to decide whether the method is appropriate to the purposes for which it is applied.

Some of the simpler and more common optimization problems in statistics can be solved easily, often by solving a system of linear equations. Many other problems, however, do not have closed-form solutions, and the solutions must be approximated by iterative methods. There are a variety of such methods (see Ng *et al.*, 2004; Spall, 2004).

Computationally Intensive Methods of Statistics

One of the most important effects of the computer is the introduction of completely new statistical methods. These methods, as all statistical methods, must be well-grounded in the theory of probability and statistics. Because of the large number of numerical computations involved in the methods, the software to implement the methods must make use of the best results from the research in statistical computing. Finally, although the statistician doing the research developing the technique is interested in the method itself, that statistician must be able to develop a computer program to implement the method. Thus, statistical research workers have come a full circle to the tradition of Fisher and the Pearsons, who developed theory and methods but could also make effective use of the current computing technology.

An overview of this area of computational statistics is given in part III of the handbook edited by Gentle *et al.* (2004). In this part of the handbook, there are sixteen articles with titles such as ‘bootstrap and resampling’, ‘Bayesian computational methods’, ‘data and knowledge mining’, and so on.

Monte Carlo Methods in Statistics

Monte Carlo methods are experiments. Monte Carlo experimentation is the use of simulated random numbers to estimate some functions of a probability distribution. A problem that does not have a stochastic component sometimes may also be posed as a problem with a component that can be identified with an expectation of some function of a random variable. The problem is then solved by estimating the expected value by the use of a simulated sample from the distribution of the random variable.

Monte Carlo methods use random numbers, so to implement a Monte Carlo method, it is necessary to have a source of random numbers. As we mentioned above, there are a number of good methods for generating random numbers.

Monte Carlo methods are used in a variety of ways in statistics. They are widely used in the development of statistical methods, very often to compare methods or

modifications of methods. Monte Carlo methods can also be used directly in statistical inference, for example, in Monte Carlo tests, and in parametric bootstrap methods (see Gentle, 2002: Ch. 2).

Resampling Methods

Although subsampling, resampling, or otherwise rearranging a given dataset cannot increase its information content, these procedures can sometimes be useful in extracting information. Randomly rearranging the observed dataset, for example, can give an indication of how unusual the dataset is with respect to a null hypothesis. This idea leads to randomization tests.

There are many useful procedures for data analysis that involve partitioning the original sample. Using subsets of the full sample, we may be able to get an estimate of the bias or the variance of the standard estimator or test statistic without relying too heavily on the assumptions that led to that choice of estimator or test statistic. It is often useful to partition the dataset into two parts and use the data in the training set or estimation set to arrive at a preliminary estimate or fit and then use the data in the validation set or test set to evaluate the fit. This kind of approach is particularly appropriate when we are unsure of our model of the data-generating process. In actual applications, of course, we are always at least somewhat unsure of our model. If the full dataset is used to fit the model, we are very limited in the extent to which we can validate the model.

Subsets of the data can be formed systematically or they can be formed as random samples from the given dataset. Sometimes, the given dataset is viewed as a set of mass points of a finite distribution whose distribution function is the same as the empirical distribution function of the given dataset. In this case, the data partitioning may be done in such a way that observations may occur multiple times in the various partitions. One of the most widely used resampling methods is the bootstrap (see Mammen and Nandi, 2004). An early use of the bootstrap, as cited by Mammen and Nandi, was in educational research. The objective was to set a confidence interval for the correlation coefficient between scores on a standard test and the grade point averages of the same subjects. The bootstrap was an appropriate tool because neither of the two variables could be assumed to follow a normal distribution.

Machine Learning

It is now common to search through datasets and compute summary statistics from various items that may indicate relationships that were not previously recognized. The individual items or the relationships among them may not have been of primary interest when the data were originally

collected. This process is sometimes called data or knowledge mining, or machine learning, particularly if predictive classification is the objective (see Wilhelm, 2004).

The objective is to discover characteristics of the data that may not be expected based on the existing theory. In the language of the database literature, the specific goals of data mining are:

- classification of observations;
- linkage analysis;
- deviation detection; and finally
- predictive modeling.

Of course, the first three of these are the objectives of any exploratory statistical data analysis. Data mining is exploratory data analysis (EDA) applied to large datasets. An objective of an exploratory analysis is often to generate hypotheses, and exploratory analyses are generally followed by more formal confirmatory procedures. The explorations in massive datasets must be performed without much human intervention. Searching algorithms need to have some means of learning and adaptively improving. This will be a major area of research for some time.

Predictive modeling uses inductive reasoning rather than the more common deductive reasoning, which is much easier to automate.

In the statistical classification of observations, the dataset is partitioned recursively. The partitioning results in a classification tree, which is a decision tree, each node of which represents a partition of the dataset. (see Zhang (2004) for a discussion of these methods).

Linkage analysis is often the most important activity of data mining. In linkage analysis, relationships among different variables are discovered and analyzed. This step follows partitioning and is the interpretation of the partitions that were formed.

It is also important to identify data that do not fit the patterns that are discovered. The deviation of some subsets of the data often makes it difficult to develop models for the remainder of the data.

Conclusions

Computational statistics has become a major subdiscipline of statistics. The computational methods of statistical computing remain an important, but somewhat specialized area of statistics. Many data analysts need only a passing knowledge of the details of the computations. Software developers or researchers who must implement a new statistical method, however, need knowledge of the field of statistical computing. A broader use of statistical computing is in designing and performing Monte Carlo studies. A substantial portion of research articles in statistics and in fields that rely on statistical

methodology include Monte Carlo studies that assess the performance of alternative statistical methods in different settings. Such studies require computer programs to generate random numbers and then to loop through multiple analyses of simulated datasets. The authors of such studies need some grounding in the methods of statistical computing.

Computationally intensive statistical methods are widely used in data analysis. Many of these methods are intrinsically nonparametric or are less dependent on distributional assumptions. Resampling methods, for example, are often used in educational research because many of the variables of interest cannot be assumed to have normal distributions. The statistical learning methods of computational statistics have come to play a major role in mining data for unexpected discoveries. Discovery of the unexpected is central to the advancement of knowledge.

Continuous Probability Distributions

S Sinharay, ETS, Princeton, NJ, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Estimate – A function of sample data used for approximating a population parameter.

Moment – The n th moment about a value c of a random variable that has a probability density function $f(x)$ is

$$\mu'_n = \int_{-\infty}^{\infty} (x - c)^n f(x) dx.$$

Continuous probability distributions, which are distributions of continuous random variables, are amenable to more elegant mathematical treatment than are discrete probability distributions. The values of variables observed in statistical applications are invariably discrete, mainly due to rounding (e.g., though weight of a person is a continuous variable, it is measured in, for example, pounds) – so, technically, continuous distributions should not be applied. However, these distributions are convenient approximations, facilitating mathematical and statistical analysis (Johnson *et al.*, 1994). For example, think of a binomial random variable X with number of trials = 30 and success probability = 0.4. To compute the probability that $X \leq 10$ using binomial probability values, one has to sum several terms of the form $\binom{30}{x} 0.4^x 0.6^{30-x}$. However, if the investigator approximates the binomial distribution (a discrete distribution) by the normal distribution (a continuous distribution), the computation is much simpler as shown as (note that the computation with current fast computers will probably take a very short time for the binomial distribution, but the same computation was not done so quickly even a couple of decades ago)

$$\begin{aligned} P(X \leq 10) &= P(X \leq 10.5) \\ &= P\left(\frac{X - 30 \times 0.4}{\sqrt{30 \times 0.4 \times 0.6}} \leq \frac{10.5 - 30 \times 0.4}{\sqrt{30 \times 0.4 \times 0.6}}\right) = \Phi(-0.56) \end{aligned}$$

where $\Phi(\cdot)$ denotes the cumulative distribution of the standard normal distribution. The value obtained using the approximation of the binomial distribution by the normal distribution is 0.29, which is the same up to 2 decimal places as that obtained without the approximation. A normal approximation helps even more in computing a confidence interval for the binomial success probability (see, as an interesting reading on the issue, Holland (1979), who commented on the tyranny of continuous models in a world full of discrete data).

A key issue with a continuous random variable is that the probability is zero that it will take any specific value. However, there is usually a positive probability that such a variable will fall within an interval. While a discrete random variable has a probability mass function, a continuous random variable has a probability density function (pdf). The integral of the pdf over an interval is the probability that the continuous random variable will fall in that interval.

In the following sections, several continuous distributions are discussed. For each distribution, its genesis, pdf, moments, estimation of the moments, methods to generate values of a random variable following that distribution, and relationships to other distributions (if any) are discussed. The normal distribution, arguably the most frequently used continuous distribution, is covered elsewhere in this encyclopedia and is not covered here.

Beta Distribution

The beta distribution is used to model continuous random variables whose range is between 0 and 1. For example, in Bayesian analyses, the beta distribution is often used as a prior distribution of the parameter p (which is bounded between 0 and 1) of the binomial distribution (see, e.g., Novick and Jackson, 1974).

The pdf of the beta distribution is given by

$$f(x; a, b) = \frac{1}{B(a, b)} x^{a-1} (1-x)^{b-1}$$

where $0 \leq x \leq 1$, $a > 0$, and $b > 0$ are called shape parameters, and $B(a, b)$ is the beta function defined as

$$B(a, b) = \frac{\Gamma(a)\Gamma(b)}{\Gamma(a+b)}$$

where $\Gamma(a)$ is the gamma function defined as $\Gamma(a) = \int_{t=0}^{\infty} t^{a-1} e^{-t} dt$.

The expectation of the beta distribution is $\frac{a}{a+b}$ and the variance is $\frac{ab}{(a+b)^2(a+b+1)}$. The parameters a and b are usually estimated by the method of moments, that is, by setting the above-mentioned mean and variance equal to the sample mean \bar{x} and sample variance s^2 and solving them for a and b . The solutions in this case are given by

$$\hat{a} = \bar{x} \left[\frac{\bar{x}(1-\bar{x})}{s^2 - 1} \right], \quad \hat{b} = (1-\bar{x}) \left[\frac{\bar{x}(1-\bar{x})}{s^2 - 1} \right].$$

It is also possible to estimate a and b using maximum likelihood, but the method requires an iterative procedure and hence is more computationally intensive.

Random numbers following the beta distribution can be generated in several ways. If V_1 and V_2 are independent and follow the χ^2 distribution (the section on the χ^2 distribution that follows will discuss generating random numbers following that distribution) with parameters c_1 and c_2 , respectively, then $\frac{V_1}{V_1 + V_2}$ follows a beta distribution with parameters $c_1/2$ and $c_2/2$. Alternatively, if Y_1, Y_2, \dots, Y_n are independent random variables following the $U(0, 1)$ (i.e., the continuous uniform distribution between 0 and 1) distribution, then the s th order statistic Y'_s follows a beta distribution with parameters s and $n - s + 1$.

A well-known application of the beta distribution (actually, that of a more general version of the distribution that has, in addition to the a and b parameters, two more parameters specifying the bounds of the distribution) in education can be found in Lord (1965), where the true test score was modeled using the beta distribution. In addition, in some applications of the Markov chain Monte Carlo (MCMC) algorithm to fit item response theory (IRT) models, the prior distribution for the guessing parameter is sometimes assumed to be the beta distribution.

Cauchy Distribution

The Cauchy distribution is often of mathematical interest due to the absence of any moments (Evans *et al.*, 2000). The pdf of the distribution is given by

$$f(x; a, b) = \left\{ \pi b \left[1 + \left(\frac{x - a}{b} \right)^2 \right] \right\}^{-1}$$

and the cumulative distribution function (cdf) is given by

$$\frac{1}{2} + \frac{1}{\pi} \tan^{-1} \left(\frac{x - a}{b} \right).$$

The mode and the median of the distribution is a , but no moments exist. The Cauchy distribution is unimodal and symmetric but has tails that are much heavier than those of the normal distribution. **Figure 1** compares the pdf of the Cauchy distribution with $a = 0$ and $b = 1$ against that of the standard normal distribution (the plot for the t distribution in the figure will be discussed later).

The ratio of two independent standard normal random variables follows a Cauchy distribution with $a = 0$ and $b = 1$. A Cauchy distribution with $a = 0$ and $b = 1$ is a special case of the Student's t distribution with one degree of freedom (df).

The sample median is a consistent estimate of the median of the Cauchy distribution. A random number following the Cauchy distribution can be generated by generating a random number R from the $U(0,1)$ distribution and then setting $F(x) = R$, where $F(x)$ is the cdf of the Cauchy distribution. The solution is given by $a + b \tan [\pi (R - 0.5)]$.

Figure 1 Plot of the pdfs of the standard normal, Cauchy and the Student's t distribution with 4 degree of freedom (df).

χ^2 Distribution

A common occurrence of the χ^2 distribution is that the sum of squares of several independent normal random variables follows a χ^2 distribution. As a consequence, several goodness-of-fit statistics follow the χ^2 distribution when the model fits the data.

A χ^2 random variable with df d and noncentrality parameter $\delta \geq 0$ has the pdf

$$f(x; d, \delta) = \frac{e^{-(x+\delta)/2}}{2^{d/2}} \sum_{j=0}^{\infty} \frac{x^{d/2+j-1} \delta^j}{\Gamma(d/2 + j) 2^{2j} j!}$$

The expectation and variance of the distribution are $d + \delta$ and $2(d + 2\delta)$, respectively. In most common applications of the distribution, the noncentrality parameter δ is 0. The distribution is then called a central χ^2 distribution, and the summation in the pdf reduces to a single term (that for $j = 0$), the mean is d and the variance is $2d$.

If d is an integer, a central χ^2 random variable with df d can be generated by generating d standard normal random numbers and adding the squares of them.

Dirichlet Distribution

The Dirichlet distribution is the multivariate generalization of the beta distribution. In Bayesian analyses, the Dirichlet distribution is often used as a prior distribution of the parameters of the multinomial distribution (see, e.g., Novick and Jackson, 1974: chapter 10–7). Consider a k -dimensional random variable $X = (X_1, X_2, \dots, X_k)$ so that the X_i 's are all positive and the sum of them is 1. If X follows the Dirichlet distribution, its pdf is given by

$$f(x_1, x_2, \dots, x_k; c_1, \dots, c_k) = \frac{\Gamma(\sum_{i=1}^k c_i)}{\prod_{i=1}^k \Gamma(c_i)} \prod_{i=1}^k x_i^{c_i-1}$$

where c_i , $i = 1, 2, \dots, k$ are the parameters of the distribution. The marginal distribution of X_i is the beta distribution with parameters c_i and $\sum_{j=1}^k c_j - c_i$. This property can be used to estimate the parameters c_i using the method of moments as discussed earlier for the beta distribution. For $k = 2$, the Dirichlet distribution becomes the beta distribution with parameters c_1 and c_2 .

To generate a random number $x = (x_1, x_2, \dots, x_k)$ from the Dirichlet distribution with c_i 's as parameters, one can generate a sequence of independent draws y_i , $i = 1, 2, \dots, k$, where y_i is a draw from the gamma distribution (to be discussed later) with parameters $b = 1$ and $c = c_i$ and compute $x_i = \frac{y_i}{\sum_{j=1}^k y_j}$, $i = 1, 2, \dots, k$.

Exponential Distribution

The exponential distribution has been employed to model variables such as the time to decay of radioactive atoms and time to failure of components with constant failure rates. The distribution is a special case of the gamma distribution that is discussed later.

The pdf of the exponential distribution is given by

$$f(x; b) = \frac{1}{b} e^{-x/b}.$$

The mean of the distribution is b and the variance is b^2 . The maximum likelihood estimate of b is the sample mean.

A random number from the exponential distribution can be generated by generating a $U(0, 1)$ random number R and then computing $-b \log(R)$.

Exponential Family of Distributions (Continuous Version)

The exponential family of distributions have pdf of the form

$$\exp \left[\sum_i A_i(\theta) B_i(x) + C(x) + D(\theta) \right]$$

where $\theta = (\theta_1, \theta_2, \dots, \theta_p)$ is the p -dimensional parameter vector of the distribution. Several continuous distributions, such as the beta, gamma, exponential, and normal distributions, are members of the exponential family of distributions. (Uniform and Cauchy distributions are examples of distributions that do not belong to the exponential family.)

The exponential family of distributions have several attractive properties, such as the set of $B_i(x)$'s being jointly

sufficient for the parameters θ . Hence, the family has been applied to several applications in education (see, e.g., Haberman (2008), for an application of the family of distributions to equating).

F Distribution

The pdf of the F distribution is given by

$$f(x; v, w, \delta) = k \frac{e^{-\delta/2} v^{v/2} w^{w/2} x^{(v-2)/2}}{B(v/2, w/2)(w + vx)^{(v+w)/2}},$$

where v and w are df's and positive integers, $\delta \geq 0$ is the noncentrality parameter, and

$$k = 1 + \sum_{j=1}^{\infty} \left(\frac{vwx/2}{w + vx} \right)^j \frac{(v+w)(v+w+2)(v+w+2j-2)}{j!v(v+2)\dots(v+2j-2)}.$$

Often, $\delta = 0$, in which case $k = 1$ and the F distribution is called the central F distribution.

The mean and variance of the central F distribution are $\frac{w}{w-2}$ and $\frac{2w^2(v+w-2)}{v(w-2)^2(w-4)}$.

If two independent χ^2 random variables χ_1^2 and χ_2^2 have df's v and w then $\frac{\chi_1^2/v}{\chi_2^2/w}$ has an F distribution with v and w df. This result can be used to generate random numbers following the F distribution.

The F distribution has often been applied in education in analysis of variance, where the ratio of the mean square of an effect and the mean square of error has an F distribution and a central F distribution under the null hypothesis that the effect is not significant.

Gamma Distribution

The gamma distribution is used to model continuous random variables whose range is between 0 and ∞ . The pdf of the gamma distribution is given by

$$f(x; b, c) = \frac{1}{b\Gamma(c)} \left(\frac{x}{b} \right)^{c-1} e^{-x/b}, \quad b \geq 0, c > 0$$

where b is called the scale parameter and c is the shape parameter. In many applications of the distribution, b is assumed to be equal to 1. The mean of the gamma distribution is bc and the variance is b^2c .

If $2c$ is an integer, then the gamma random variable is half of a χ^2 random variable with $2c$ df. If $c = 1$, then the gamma distribution becomes the exponential distribution. If V_1 and V_2 are gamma random variables, with $b = 1$ and $c = c_1$ and c_2 , respectively, then $\frac{V_1}{V_1 + V_2}$ follows a beta distribution with parameters c_1 and c_2 .

By the method of moments, the estimate of b is $\frac{\bar{x}^2}{\bar{x}}$ and that of c is $\left(\frac{\bar{x}}{\bar{x}^2} \right)^2$. It is possible to estimate the parameters

using the maximum likelihood method, but that requires the use of an iterative algorithm.

If c is an integer, then $-b \prod_{i=1}^c R_i$ follows a gamma distribution with parameters b and c , where the R_i 's are independent $U(0, 1)$ random variables – this result can be used to generate random numbers following the gamma distribution.

The reciprocal of a gamma random variable follows a distribution called the inverse gamma distribution. In several applications of Bayesian methods to IRT models, the prior distribution for the variance parameters is often assumed to be the inverse gamma distribution (see, e.g., Bradlow *et al.*, 1999).

Lognormal Distribution

If a random variable V has a normal distribution with mean μ and variance σ^2 , then e^V has a lognormal distribution with parameters μ and σ^2 . In other words, if a variable has a lognormal distribution, then its logarithm has a normal distribution. The pdf of the distribution is given by

$$f(x; \mu, \sigma^2) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x)-\mu}{\sigma}\right)^2}$$

where x and σ are both positive. If X follows a lognormal distribution with parameters μ and σ^2 , then $Y = e^a X^b$ follows a lognormal distribution with parameters $a + b\mu$ and $b^2\sigma^2$.

The expectation and variance of the lognormal distribution are given by

$$E(x) = e^{\mu + \frac{\sigma^2}{2}}, \quad V(x) = e^{2\mu + \sigma^2} (e^{\sigma^2} - 1).$$

Using its relationships to the normal distribution, the parameters of the lognormal distribution from a sample x_1, x_2, \dots, x_n of draws from the distribution can be estimated as

$$\hat{\mu} = \frac{1}{n} \sum \log(x_i), \quad \hat{\sigma}^2 = \frac{1}{n-1} \sum (\log x_i - \hat{\mu})^2.$$

The easiest way to generate random numbers from a lognormal distribution with parameters μ and σ^2 is to generate random numbers from a normal distribution with mean μ and variance σ^2 and then exponentiate them.

In some applications of Bayesian methods to IRT models, the prior distribution on the slope parameters is sometimes assumed to be a lognormal distribution. For example, the PARSCALE software program, which is used to fit IRT models by several operational testing programs, assumes a lognormal distribution as the prior distribution for the slope parameters (see e.g., du Toit, 2003).

Student's t Distribution

The t distribution is often applied in testing the hypothesis for normally distributed data. For example, for testing the hypothesis that the mean of a normal distribution is 0, the standard test statistic used has a t distribution under the null hypothesis.

The pdf of the distribution is given by

$$\frac{v^{v/2} e^{-\delta^2/2}}{\Gamma(v/2) \pi^{0.5} (v + x^2)^{(v+1)/2}} \sum_{i=0}^{\infty} \Gamma\left(\frac{v+i+1}{2}\right) \frac{(x\delta)^i}{i!} \left(\frac{2}{v+x^2}\right)^{i/2}$$

where v is the df and δ is the noncentrality parameter.

The mean of the distribution is $\frac{\delta(v/2)^{1/2} \Gamma((v-1)/2)}{\Gamma(v/2)}$ and the variance is given by

$$\frac{v}{v-2} (1 + \delta^2) - \frac{v}{2} \delta^2 \left(\frac{\Gamma((v-1)/2)}{\Gamma(v/2)} \right)^2.$$

If the noncentrality parameter is 0, then the distribution is called a central t distribution that has mean 0 and variance $\frac{v}{v-2}$.

The t distribution has a much heavier tail than the normal distribution for small df. **Figure 1** shows a comparison of the pdf of the Cauchy distribution with $a = 0$ and $b = 1$ (that is a special case of the Student's t distribution with 1 df) and that of the Student's t distribution with 4 df against that of the standard normal distribution. The t distribution with 1 df (or the Cauchy distribution) has the heaviest tail followed by that with 4 df.

For large df, the central t distribution becomes close to the standard normal distribution. The square of a central t distribution is the distribution of the ratio of two independent χ^2 random variables, the first having 1 df (note that a χ^2 random variable can be expressed as the square of a standard normal random variable) and the other having v df. It also has an F distribution with df's 1 and v .

To generate a random number following the central t distribution with v df, one can compute the ratio of a standard normal random number and the square root of Y/v , where Y is a random number following the χ^2 distribution with v df and both of these random numbers are generated independently of each other. (Note that Y can be generated as the sum of squares of v independent standard normal random numbers.)

Uniform Distribution

The uniform or rectangular distribution is the distribution that uniform random numbers follow. In addition, this distribution is widely used as the basis for the generation of random numbers from other continuous statistical distributions (Evans *et al.*, 2000).

The uniform distribution with range (a, b) , often denoted as $U(a, b)$, has the pdf $\frac{1}{b-a}$ if $a \leq x \leq b$ and 0 otherwise.

The cdf is 0 if $x \leq a$, $\frac{x-a}{b-a}$ if $a \leq x \leq b$, and 1 if $x \geq b$. When $a = 0$ and $b = 1$, the uniform distribution becomes the standard or unit uniform distribution.

The mean of the distribution is $\frac{a+b}{2}$ and the variance is $\frac{(b-a)^2}{12}$.

For any continuous random variable Y , its cdf $F(y)$ follows a $U(0,1)$ distribution and $F^{-1}(R)$ has the cdf F for R following the $U(0,1)$ distribution. This property is used to generate random numbers from other continuous distributions starting from standard uniform random numbers.

The method of moments estimates of a and b are $\bar{x} - 3^{1/2}s$ and $\bar{x} + 3^{1/2}s$, respectively. To generate a random number x following a $U(a, b)$ distribution, one has to generate a $U(0,1)$ random number R , and then use the transformation $x = a + (b - a)R$.

Wishart Distribution

The Wishart distribution is the multivariate generalization of the χ^2 random variable. It is the probability distribution of the maximum-likelihood estimator (MLE) of the covariance matrix of a multivariate normal distribution. A k -dimensional random variable X following the Wishart distribution has a pdf proportional to

$$e^{\left[-\frac{1}{2}\text{tr}(\Sigma^{-1}X)\right]} |X|^{\frac{n-k-1}{2}}$$

where Σ is a $k \times k$ matrix, n is the df, $\text{tr}(A)$ is the trace of matrix A , and $|A|$ is the determinant of the matrix A . The distribution has a mean of $n\Sigma$.

If Y_1, Y_2, \dots, Y_n are n k -dimensional random numbers independently drawn from a multivariate normal distribution with mean vector μ and variance matrix Σ , then the distribution of $\sum_{i=1}^n Y_i Y_i'$ is k -dimensional Wishart with k df and parameter Σ . This result can be used to generate random matrices following the Wishart distribution.

The inverse of a random variable following a Wishart distribution follows the inverse Wishart distribution. The inverse Wishart distribution is often assumed to be the prior distribution on the variance matrix in a Bayesian approach to IRT modeling (Johnson and Sinharay, 2005).

Conclusions

Among the numerous continuous statistical distributions, this article provides a brief overview of a few distributions

that have found applications in the field of education (see, e.g., Evans *et al.*, 2000; Johnson *et al.*, 1994; and Kotz *et al.*, 2000, for more detailed descriptions of these and many more continuous distributions). Though an observed random variable is never continuous in the true sense of the term (due to rounding), the continuous random variables describe the data in a satisfactory manner in several statistical applications. The choice of the specific distribution to be used in a specific application depends on several issues. If a specific distribution is used in practice for data of the type an investigator has (e.g., a Dirichlet distribution is often applied in practice to model the probabilities from a multinomial distribution), that distribution should be the first choice. If such knowledge is lacking, a sensible approach is to graphically plot the data and try to find a distribution that is expected to describe the data adequately. After fitting a distribution to a data set, methods of goodness-of-fit can be used to examine whether the distribution provides an adequate description of the data set.

Glossary

Chi-square distance – The weighted Euclidean distance measure between row (or column) profiles of a table, where each squared difference between profile elements is divided by the corresponding element of the average profile.

Contingency table – A cross-tabulation of a set of objects according to two categorical variables; hence, the grand total of the table is the number of objects.

Correspondence analysis – A method of displaying the rows and columns of a table as points in a spatial map, with a specific geometric interpretation of the positions of the points in terms of similarities and differences between rows, the similarities and differences between columns, and the association between rows and columns.

Inertia – The weighted sum of squared distances of a set of points to their weighted average; a measure of variance of a set of multidimensional points, each weighted by its mass.

Mass – The marginal total of a row or a column of a table, divided by the grand total of the table; used as weights in correspondence analysis.

Profile – A row or a column of a table divided by its total; the profiles are the points visualized in correspondence analysis.

Correspondence analysis (CA) is a variant of principal component analysis (PCA) aimed primarily at categorical data, for example, aggregate count data in contingency tables or individual-level responses in questionnaire surveys. Emphasis is placed on visual maps that result from the method, displaying the rows and columns as points in a joint map in which distances and relative positions of points have a specific interpretation. Since most data in the social sciences are categorical by nature, CA is a valuable tool for exploring relationships between variables and comparing individuals or groups of individuals, always in an intuitive graphical format. The theory of CA has a long history (for historical details, see Nishisato, 2006), while the graphical context and interpretation are due to Benzéeri (1973). Benzéeri's contribution was inspired by Karl Pearson's geometric approach to PCA (Pearson, 1901) and Louis Guttman's work on psychometric scaling (Guttman, 1941).

Two forms of CA dominate. First, simple CA is the analysis of a table of frequencies, usually a cross-tabulation of two categorical variables. Second, multiple correspondence analysis (MCA) is the analysis of more than two categorical variables, and can be interpreted as a form of PCA of nominal categorical data. Another way of distinguishing the two approaches is that CA analyzes relationships between two variables, whereas MCA analyzes relationships within a larger set of variables. In fact, both approaches use the same algorithm for their solution, differing only in the coding of the data fed to the algorithm. After an introduction to the basic concepts of simple CA, using a small table, examples of these two forms of the method are given.

Simple CA

The following table summarizes the responses of 315 people in the USA, classified into five education groups, to the question: "How much confidence do you have in your country's education system?" Possible answers were "A great deal," "Quite a lot," "Not much," and "None at all", and in the table below, the last two categories have been combined so that the table has three columns.

	<i>Great deal</i>	<i>Quite a lot</i>	<i>Not much/ none at all</i>	<i>Sums</i>
E1-some primary	3	10	6	19
E2-primary completed	14	47	23	84
E3-some secondary	33	31	20	84
E4-secondary completed	43	44	13	100
E5-some (or completed) tertiary	17	9	2	28
Sums	110	141	64	315

The general idea is to define a set of row or column points in multidimensional space, decide on a distance function between the points and whether the points should be differentially weighted, and then, for interpretation, project the points onto a low-dimensional subspace which comes closest to all the points. In CA, the vectors of relative frequencies, or profiles, of the rows (or of the

columns) define the points: that is, the rows (or columns) divided by their respective sums. The following explanation will be in terms of the row profiles, but exactly the same argument applies to the columns. The profiles of the rows, including the profile of the column sums, labeled average, are given next:

	<i>Great deal</i>	<i>Quite a lot</i>	<i>Not much/none at all</i>
E1-some primary	0.158	0.526	0.316
E2-primary completed	0.167	0.560	0.274
E3-some secondary	0.393	0.369	0.238
E4-secondary completed	0.430	0.440	0.130
E5-some (or completed) tertiary	0.607	0.321	0.071
Average	0.349	0.448	0.203

(e.g., $0.158 = 3/19$ (first cell, first row), and $0.349 = 110/315$ (first cell, last row) – we shall explain below in what sense the last row is an average of the elements in the table.) As the elements of each row profile add up to a constant 1, these three-dimensional profiles are points in a plane; in fact, they are points lying in a two-dimensional triangle joining the unit points for the three categories, namely $[1\ 0\ 0]$, $[0\ 1\ 0]$, and $[0\ 0\ 1]$. This is the triangular, or barycentric, coordinate system, shown in **Figure 1**.

A convenient way of thinking about barycentric coordinates is that each profile is situated at the weighted average, or centroid, of the corners of the triangle, each of which represents the purest or most extreme group of respondents (e.g., corner 1 with values $[1\ 0\ 0]$, corresponds to 100% response in the first category, a great deal). Thus, education group E1, for example, with profile values 0.158, 0.526, and 0.316, lies further from the first corner (a great deal), but closer to the second (quite a lot) because its position is at $(0.158 \times \text{corner 1}) + (0.526 \times \text{corner 2}) + (0.316 \times \text{corner 3})$.

There are two other important concepts in CA: the way profiles are weighted and the measure of distance between profiles. The original row sums of the table (19, 84, etc.) are used as weights, so that each education group is weighted proportional to its subgroup size. In fact, the weights are defined by the relative sums: $0.060 = 19/315$, $0.267 = 84/315$, etc., which are called the (row) masses in CA – the masses, like the profiles, add up to 1. The average profile described above is, thus, the centroid of the row profiles, where each row profile is weighted by its respective mass. As far as the inter-profile distance is concerned, a standardization of the column categories is used which is appropriate for frequency data, with the spin-off that the spatial dispersion of the points will be related to the chi-square statistic for the contingency table

Figure 1 The education profiles and the average profile shown as points in a triangular coordinate system. The vertices of the triangle are the unit points in the underlying three-dimensional Euclidean space.

(see below). In contrast to PCA, where standardization is usually performed by dividing by the square root of the variance of each variable (appropriate for interval-scale data), in CA, the relative frequencies for a category are divided by the square root of the average. For example, in the table above, the values in the first column (0.158, 0.167, etc.) are divided by the square root of 0.349, which is 0.591, the second column is divided by $\sqrt{0.448} = 0.669$, and the last column by $\sqrt{0.203} = 0.451$. With this standardization, the categories of lower average frequency (and usually lower variance) have their profile coordinates divided by smaller values and increase in value more than those associated with categories with higher frequency. Distances between profiles are calculated using the usual Euclidean distance computed on their standardized values – the resulting distance is called the chi-square distance. Geometrically, this changes the equilateral triangle space of **Figure 1** to a triangle with unequal sides – all the corners are stretched out, where the stretching is more for categories of lower frequency.

With this definition of row profiles, row masses, and inter-row distances, the weighted sum of squared distances of the points to their average is exactly the chi-square statistic for the table divided by the grand total of the table, a quantity called the inertia in CA. We, thus, have a multidimensional geometric picture of the row–column association as a cloud of points in space: the further they are away from their average, the higher the inertia, and thus, the chi-square. It is the inertia that is explained in CA, just like the total variance is explained in PCA.

Generalizing this geometry to higher dimensions is straightforward: for four columns, the chi-squared space of the profiles is an irregular tetrahedron in three dimensions (in the application below, we shall give an animated three-dimensional graphical display to show this geometry).

In general, profiles with p elements lie in a $p - 1$ dimensional space. In this initial example, which lies exactly in two dimensions, no dimension reduction is necessary and CA simply rotates the display to principal axes (**Figure 2**). Here, we can see that the triangle formed by the response categories is no longer equilateral, which as described above, is due to the standardization to induce the chi-square distance between profiles.

Computation of the principal axes in order to achieve dimension reduction uses an eigenvalue/eigenvector routine, as in PCA, or more elegantly using the singular-value decomposition for rectangular matrices. These algorithms identify optimal maps, that is, spaces of lower dimensionality, usually two-dimensional planes, which best fit the points. CA and PCA do these in similar ways, by least squares, the only difference being in the definition of distance and the fact that in CA, the points are weighted, which varies the importance of each profile point in the search for a low-dimensional solution – hence, higher mass points are more influential than lower mass points in determining the solution. An equivalent way to think of dimension reduction is reminiscent of the objective of PCA to capture the most variance along the principal axes. In CA, it is the inertia which is being explained optimally along the principal axes. The format of the

results of PCA and CA is essentially the same, for example, there are inertias and percentages of inertia explained on each principal axis, as in **Figure 2**. A special property of CA is that the theory explained above in terms of row profiles is identical for the column profiles, which have the same inertia and the same decomposition along principal axes.

The coordinates of profiles projected onto principal axes are called principal coordinates (e.g., the coordinates of the education groups in **Figure 2**). The coordinates of the unit points, or vertices, projected onto principal axes, are called standard coordinates (e.g., the response category points in **Figure 2**). The map of **Figure 2** is called an asymmetric map of the rows (or row principal map) because it shows the rows in principal coordinates and columns in standard coordinates. In an asymmetric map, the barycentric property again holds: for example, in **Figure 2**, every profile lies at the weighted average of the response categories, where the weights are the profile elements. Thus, education group E5, with profile elements 0.607, 0.321, and 0.071, lies closest to the response category “a great deal” because of its largest weight of response on that category. In examples where the inertia is low, that is, where there are small differences between the profiles, the profiles tend to bunch up around their mean,

Figure 2 The CA solution corresponding to **Figure 1**, where the profiles have been standardized to give chi-square distances (hence the stretched triangle of the category vertices), and then rotated to principal axes. The inertias along principal axes and their percentages are shown – 100% of the inertia is explained because these data are exactly two-dimensional.

Figure 3 Asymmetric CA map of **Table 1**, showing the country profiles projected onto the plane of the first two principal axes (i.e., principal coordinates), as well as the extreme corners of the profile space (i.e., standard coordinates). The total inertia is 0.1628, of which 92.6% is represented in the map.

and the asymmetric map is impractical (e.g., see the application in **Figure 3**). In this situation, either the profiles need to be magnified in scale or – thanks to the symmetry of the row and column problems – a symmetric map is often reported where both rows and columns are in principal coordinates, thus, having the same dispersions along principal axes.

Application of Simple Correspondence Analysis

Table 1 gives the percentage responses to the question on the education system by samples of respondents from 24 European countries, with the inclusion of Russia and Turkey (data from the World Values Survey). We do not analyze raw frequencies in this case because the original sample sizes in each country do not reflect a valid weighting system for the countries – using percentages means that each country is equally weighted in the analysis, which is preferable.

Two versions of the two-dimensional CA map are shown in **Figures 3** and **4** respectively. In the asymmetric map of **Figure 3**, the four vertices representing the response categories are shown projected onto the optimal map of the countries. The bunching up of most of the country points near the average is clearly seen, and it is easier to distinguish them in the symmetric map of **Figure 4** where the response category points are represented in principal coordinates (these are the profiles of the columns). The response category “none at all” at upper left is well separated from the other categories because of Turkey and Greece, which have very high proportions of this response.

Among the other countries there is a gradient from “not much” (lower left) to “a great deal” (upper right), with Ireland, Poland, and Romania in the most favorable positions and Czech Republic in the least favorable position. Looking at Greece and Turkey again, notice that while both have the highest frequencies of the “none-at-all” response, Turkey, being higher up in the map, must have a relatively high number of the response “a great deal,” indicating a society split on this issue (i.e., more than average on both extremes of the response scale), while Greece is lower down on the left, indicating a society that is consistently lacking in confidence in its education system. These deductions from the map can be verified in the data of **Table 1**.

Multiple Correspondence Analysis

MCA deals with a set of more than two categorical variables, generally variables on similar scales, where interest is focused on inter-variable associations within the set. MCA can be defined in many equivalent ways, and here, we give the definition in terms of the indicator matrix, which is the respondents-by-categories matrix of dummy variables. Each categorical variable generates as many zero/one dummy variables as response categories: these variables form the columns of the indicator matrix. If there are Q variables in a questionnaire, for example, each row of the matrix will consist of zeros, except for Q ones, indicating the set of response categories for that respondent. MCA is the application of CA to this indicator matrix.

Table 1 Percentage responses by citizens of 24 countries to the question: “How much confidence do you have in your education system?”

		<i>Confidence in education</i>			
<i>Country</i>		<i>A Great deal</i>	<i>Quite a lot</i>	<i>Not much</i>	<i>None at all</i>
Austria	AU	29.38	56.90	12.86	0.86

**Figure 4** Symmetric CA map of Table 1, showing the country profiles as well as the response category profiles projected onto the plane of the first two principal axes (both rows and columns in principal coordinates).

Application of Multiple Correspondence Analysis

To illustrate MCA, we consider the responses in the Spanish sample to three questions: confidence in the education system, as before, confidence in the social security system, and confidence in the healthcare system. The sample consists of 1181 respondents, and each of the three variables has four response categories (the levels of confidence, now labeled 1 – a great deal, to 4 – none at all) as well as a missing value category (labeled 9), thus, five categories for each of the three variables. As the data are analyzed at a nominal level, the missing response can be included simply as an additional category. Thus, in this application, there are 15 categories in total, giving an indicator matrix with 15 columns. Part of the indicator matrix is shown in the upper part of **Table 2**. The best two-dimensional map is given in **Figure 5**, showing the categories in standard coordinates (once again as vertices of an irregular simplex) and the respondents in principal coordinates labeled by their response combination; for example, 439 represents those respondents with confidence none at all for education, not much for social security, and missing response for healthcare). Since each row of the indicator matrix has a profile with elements 0 apart from three positive values of $1/3$ (i.e., in general, Q values of $1/Q$, where there are Q questions), the barycentric property implies that each individual lies at the ordinary average of his or her response categories. For example, the point 439 in **Figure 5** is at the average position of the categories E-4, S-3, and H-9. Of the $5^3 = 125$ possible response combinations, there are 78 observed in this data set, some being much more frequent than others; hence, the labels in **Figure 5** represent varying numbers of respondents piling up at each of the points. For example, the response sets giving the same responses to all questions are 111 – 61 respondents, 222 – 314, 333 – 123, 444 – 16, and 999 – 8. These response sets result in the strong associations between the response categories that have the same wording, clearly visible in **Figure 5**. Otherwise, we notice a typical arch effect inside the simplex, showing the responses in their ordinal sequence, from 1 (upper left) to 2 and 3 (lower down), and 4 (upper right). Individuals inside the arch (e.g., groups with responses such as 114, 141, and 414) have a mixture of the extreme responses; for example, 114 represents respondents with very high confidence in both education and social security, but none at all in healthcare.

Supplementary Points

An important concept in CA and MCA is that of a supplementary point, that is a data vector which contains external explanatory information and which can be represented in

a map to aid the interpretation. Since points are weighted by their masses, the best way to think about supplementary, or passive, points is that they are in the original data set but have zero mass, hence not influencing the solution but projected onto the map determined by the active points that do have positive mass. For example, in **Table 2**, additional rows have been added, which are the cross-tabulations of gender (two categories) and age (six categories) with the three questions. The profiles of these rows are exactly the averages of the respondents corresponding to the respective categories, and can be projected onto the same map, as shown in **Figure 6** (because they lie close to the origin, a magnification of their positions is shown). For example, the point a1 corresponding to the youngest age group lies exactly at the mean position of the subgroup of respondent points in this age group. We can see, for example, that the three first age groups are together toward the side of the map that is less confident, while the trend in the older groups is toward being more confident. Whether these conclusions are significant or not can be judged by regular statistical tests (e.g., univariate or multivariate analysis of variance, or permutations tests).

Contributions

Apart from the visualizations afforded by CA, there are various numerical diagnostics that assist with the interpretation of the results. These are all thanks to the decomposition of the total inertia, which is a weighted sum of squares, into parts due to the rows, or due to the columns, or due to the dimensions of the solution. Each row (or column) makes a part contribution to the principal inertia of each dimension: these contributions, usually expressed as proportions, provide information about which rows (or columns) have played the most important role in determining the dimension. Conversely, each dimension contributes to the inertia of a row (or column): these contributions, again expressed in relative amounts, provide information about the quality of display of each row (or column) in the space of the solution, for example, it can show easily which points are not well represented in the map.

Data Coding

An important feature of the CA approach is the wealth of coding schemes which allow different data types to be transformed so that CA is suitable as a visualization method. Here are two examples of these:

1. *Doubling*. For ratings, rankings, and paired comparisons, each variable engenders two recoded variables that can be thought of as positive and negative poles. For example,

Table 2 Data for MCA of individual response data, as well as aggregated counts for gender and age groups; all categorical data are coded as dummy variables, while the biographical categories are supplementary row points which will be at the averages of the respondents in their respective categories

	<i>E1</i>	<i>E2</i>	<i>E3</i>	<i>E4</i>	<i>E9</i>	<i>S1</i>	<i>S2</i>	<i>S3</i>	<i>S4</i>	<i>S9</i>	<i>H1</i>	<i>H2</i>	<i>H3</i>	<i>H4</i>	<i>H9</i>	<i>m</i>	<i>f</i>	<i>a1</i>	<i>a2</i>	<i>a3</i>	<i>a4</i>	<i>a5</i>	<i>a6</i>

⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮								

Variables: *E* – Education system; *S* – Social security; *H* – Healthcare.

Levels of confidence: 1 – a great deal; 2 – quite a lot; 3 – not much; 4 – none; 9 – missing.

Figure 5 MCA of the individual-level responses to three questions. Percentages of inertia are calculated in a different way in MCA (e.g., see Greenacre, 2007). Here, the percentages are 34.8% and 26.4% respectively on axes 1 (horizontal) and 2 (vertical), that is, 61.2% explained in the solution.

Figure 6 Supplementary points gender and age group in the MCA solution of **Figure 5**.

a value of 2 on a five-point rating scale (negative 1 to positive 5, e.g., disagree to agree) is coded as two values, 1 and 3, respectively, since 2 has one scale point on the rating scale below it and three scale points above it. In a ranking of 10 objects (where 1 is the most preferred, say), a ranking of 3 would be coded $10 - 3 = 7$ and $3 - 1 = 2$, respectively, since there are 7 objects less preferred and 2 more preferred. Notice that the idea is to obtain measures of association between the respondent and the doubled variables, hence, the positive pole in this last example has the higher value of 7 because the object is highly ranked.

2. *Fuzzy coding.* Continuous variables can be cut up into intervals and so converted into categorical data: for example, a variable such as temperature can be divided into three intervals using two cutpoints, so that a value of 2 represents a medium temperature, eventually coded in dummy variable form as $[0 \ 1 \ 0]$. This crisp coding clearly loses much information, and an alternative is fuzzy coding, where the value is coded using so-called membership functions: for example, a recoded value of $[0 \ 0.692 \ 0.308]$ would indicate a temperature somewhat higher up in the medium category toward the high category. The fuzzy coded values also add up to 1 and so may be used in conjunction with other dummy-coded categorical data in a CA.

Special Topics

Several variants of CA and MCA have been developed, especially in the social and environmental sciences for special situations:

1. *Subset CA and MCA.* Especially in survey research, we would like to analyze certain subsets of question responses, for example, just the disagree responses, or all the substantive responses excluding the missings. As CA uses the marginal sums as weights, the simple use of a reduced table leads to problematic situations because the margins change. This can be easily remedied, however, by maintaining the original margins of the full table whenever a subtable is analyzed, resulting in what is called subset CA, or subset MCA as the case may be.
2. *Canonical CA.* Especially in ecological applications, tables of counts are analyzed – typically, abundances of species at sampling locations – and additional variables are observed for each sample. Ecologists are interested in the variance of the abundance data that can be explained by these external variables, so CA is performed in a subspace that is restricted to be related (usually linearly related) to the external variables – this is called canonical CA (CCA). As a special case, if we have one external categorical variable, for example, regions of sampling, CCA is equivalent to aggregating

the counts of each species within each region and then performing CA.

3. *Analysis of square asymmetric tables:* Tables where the rows and columns represent the same sets of objects deserve special treatment, for example, mobility tables, transition matrices between states in behavioral studies, and brand switching in marketing. Usually, the diagonal dominates the data and obscures subtler asymmetrical features off the diagonal. One solution is to split the table as the sum of a symmetric and a skew-symmetric part, and analyze these separately.
4. *Statistical inference.* In simple CA, when the data form a contingency table based on random sampling, there are certain asymptotic results in the literature, based on the multivariate normal approximation to the multinomial distribution, that permit inference to be made about the parts of inertia explained by each dimension, as well as tests whether points differ significantly from the average point at the origin of the map, or differ from one another in pairwise tests. Resampling methods, such as the bootstrap and permutation testing, can estimate the confidence regions of points and test hypotheses in a less formal way. The CA model can also be estimated using maximum likelihood, in which case the interpretation is not based on projective geometry as in CA, but nevertheless permits more rigorous hypothesis testing.

Glossary

Association rule mining – A class of data mining methods where there is automatic discovery of if–then rules of the form that if some set of variable values is found, another variable generally has a specific value.

Automated experimentation – A method used to create data where causal inference is facilitated. In this method, a pedagogical choice is randomly made by learning software in situations where multiple pedagogical choices are feasible.

Causal data mining – A class of data mining methods that attempts to infer causal structure between events within correlational data, using information about timing of events and their covariance, particularly in relation to other variables.

Classification – A class of data mining methods that attempts to predict the value of some variable, where the predicted variable is a binary or categorical variable.

Clustering – A class of data mining methods whose goal is to find data points that are similar to each other, splitting the full data set into a set of groups (such as groups of courses, groups of students, or groups of actions).

Correlation mining – A class of data mining methods whose goal is to find particularly strong linear correlations (positive or negative) between variables.

Data mining – The field of discovering novel and potentially useful information from large amounts of data. (Also see: educational data mining.)

Density estimation – The estimation of the probability density function underlying a data distribution.

Educational data mining – The area of scientific inquiry centered around the development of methods for making discoveries within the unique kinds of data that come from educational settings, and using those methods to better understand students and the settings which they learn in.

Gaming the system – Attempting to succeed in an interactive learning environment by exploiting properties of the system rather than by learning the material, including behaviors such as systematic guessing, hint abuse, spam posting, and point cartels.

Learning decomposition – A type of relationship mining, within the broader rubric of educational data mining. In learning decomposition, exponential learning curves are fit to performance data, relating student success to the amount of each type of pedagogical support a student has received (with an empirically determined weight for each type of support). The weights indicate how effective each type of pedagogical support is for improving learning. Relationships are only viewed as definitively causal if automated experimentation was used.

Q-matrix – A mapping between items and knowledge components (such as skills or concepts).

Regression – A class of data mining methods whose goal is to predict a quantitative dependent variable as a function of other variables.

Relationship mining – A class of data mining methods whose goal is to discover relationships between variables, in a data set with a large number of variables. This may take the form of attempting to find out which variables are most strongly associated with a single variable of particular interest, or may take the form of attempting to discover the relationship between any two variables in a large data set. Broadly, there are three types of relationship mining: association rule mining, correlation mining, and causal data mining.

Slip – A slip occurs when a student obtains an incorrect answer despite knowing the skills or concepts necessary to obtain a correct answer.

Introduction

Data mining, also called knowledge discovery in databases (KDD), is the field of discovering novel and potentially useful information from large amounts of data. Data mining has been applied in a great number of fields, including retail sales, bioinformatics, and counter-terrorism. In recent years, there has been increasing interest in the use of data mining to investigate scientific questions within educational research, an area of inquiry termed educational data mining (EDM). EDM is defined as the area of scientific inquiry centered around the development of methods for making discoveries within the unique kinds of data that come from educational settings, and using those methods

to better understand students and the settings which they learn in.

EDM methods often differ from methods from the broader data mining literature, in explicitly exploiting the multiple levels of meaningful hierarchy in educational data. Methods from the psychometrics literature are often integrated with methods from the machine learning and data mining literatures to achieve this goal.

For example, in mining data about how students choose to use educational software, it may be worthwhile to simultaneously consider data at the keystroke level, answer level, session level, student level, classroom level, and school level. Issues of time, sequence, and context also play important roles in the study of educational data.

EDM has emerged as an independent research area in recent years, culminating in 2008 with the establishment of the annual International Conference on Educational Data Mining, and the *Journal of Educational Data Mining*.

Advantages Relative to Traditional Educational Research Paradigms

EDM offers several advantages, vis-à-vis more traditional educational research paradigms, such as laboratory experiments, in vivo experiments, and design research.

In particular, the advent of public educational data repositories, such as the Pittsburgh Science of Learning Center (PSLC) DataShop and the National Center for Education Statistics (NCES) data sets, has created a base which makes EDM highly feasible. In particular, the data from these repositories are often both ecologically valid (inasmuch as they are data about the performance and learning of genuine students, in genuine educational settings, involved in authentic learning tasks), and increasingly easy to rapidly access and begin research with. Balancing feasibility with ecological validity is often a difficult challenge for researchers in other educational research paradigms. By contrast, researchers who use data from these repositories can dispense with traditionally time-consuming steps such as subject recruitment (e.g., recruitment of schools, teachers, and students), scheduling of studies, and data entry (since data are already online). While the use of previously collected data has the potential to limit analyses to questions involving the types of data collected, in practice data from repositories or prior research have been useful for analyzing research questions far outside the purview of what the data were originally intended to study, particularly given the advent of models that can infer student attributes (such as strategic behavior and motivation) from the type of data in these repositories.

This increase in speed and feasibility has had the benefit of making replication much more feasible. Once a construct of educational interest (such as off-task behavior,

or whether or not a skill is known) has been empirically defined in data, it can be transferred to new data sets. The transfer of constructs is not trivial – often, the same construct can be subtly different at the data level, within data from a different context or system – but transfer learning and rapid labeling methods have been successful in speeding up the process of developing or validating a model for a new context. This has led to many EDM analyses being replicated across data from several learning systems or contexts.

Increasingly, the existence of data from thousands of students, having broadly similar learning experiences (such as using the same learning software), but in very different contexts, gives leverage that was never before possible, for studying the influence of contextual factors on learning and learners. It has historically been difficult to study how much the differences between teachers and classroom cohorts influence specific aspects of the learning experience; this sort of analysis becomes much easier with EDM. Similarly, the concrete impacts of fairly rare individual differences have been difficult to statistically study with traditional methods (leading case studies to be a dominant research method in this area) – EDM has the potential to extend a much wider tool set to the analysis of important questions in individual differences.

Main Approaches

There are a wide variety of current methods popular within EDM. These methods fall into the following general categories: prediction, clustering, relationship mining, discovery with models, and distillation of data for human judgment (Table 1). The first three categories are largely acknowledged to be universal across types of data mining (albeit in some cases with different names). The fourth and fifth categories achieve particular prominence within EDM.

Prediction

In prediction, the goal is to develop a model which can infer a single aspect of the data (predicted variable) from some combination of other aspects of the data (predictor variables). Prediction requires having labels for the output variable for a limited data set, where a label represents some trusted ground-truth information about the output variable's value in specific cases. In some cases, however, it is important to consider the degree to which these labels may in fact be approximate, or incompletely reliable.

Prediction has two key uses within EDM. In some cases, prediction methods can be used to study what features of a model are important for prediction, giving information about the underlying construct. This is a common approach in programs of research that attempt to predict student educational outcomes (Romero *et al.*, 2008), without

Table 1 The primary categories of educational data mining

<i>Category of method</i>	<i>Goal of method</i>	<i>Key applications</i>
Prediction	Develop a model which can infer a single aspect of the data (predicted variable) from some combination of other aspects of the data (predictor variables)	Detecting student behaviors (e.g., gaming the system, off-task behavior, and slipping); developing domain models; predicting and understanding student educational outcomes
Clustering	Find data points that naturally group together, splitting the full data set into a set of categories	Discovery of new student behavior patterns; investigating similarities and differences between schools
Relationship mining	Discover relationships between variables	Discovery of curricular associations in course sequences; discovering which pedagogical strategies lead to more effective/robust learning
Discovery with models	A model of a phenomenon developed with prediction, clustering, or knowledge engineering, is used as a component in further prediction or relationship mining.	Discovery of relationships between student behaviors, and student characteristics or contextual variables; analysis of research question across wide variety of contexts
Distillation of data for human judgment	Data are distilled to enable a human to quickly identify or classify features of the data.	Human identification of patterns in student learning, behavior, or collaboration; labeling data for use in later development of prediction model

predicting intermediate or mediating factors first. In a second type of usage, prediction methods are used in order to predict what the output value would be in contexts where it is not desirable to directly obtain a label for that construct (e.g., in previously collected repository data, where desired labeled data may not be available, or in contexts where obtaining labels could change the behavior

being labeled, such as modeling affective states, where self-report, video, and observational methods all present risks of altering the construct being studied).

For example, consider research attempting to study the relationship between learning and gaming the system, attempting to succeed in an interactive learning environment by exploiting properties of the system rather than by learning the material. If a researcher has the goal of studying this construct across a full year of software usage within multiple schools, it may not be tractable to directly assess, using nondata-mining methods, whether each student is gaming, at each point in time. Baker *et al.* (2008b) developed a prediction model by using observational methods to label a small data set, developing a prediction model using automatically collected data from interactions between students and the software for predictor variables, and then validating the model's accuracy when generalized to additional students and contexts. They were then able to study their research question in the context of the full data set.

Broadly, there are three types of prediction: classification, regression, and density estimation. In classification, the predicted variable is a binary or categorical variable. Some popular classification methods include decision trees, logistic regression (for binary predictions), and support vector machines. In regression, the predicted variable is a continuous variable. Some popular regression methods within EDM include linear regression, neural networks, and support vector machine regression. In density estimation, the predicted variable is a probability density function. Density estimators can be based on a variety of kernel functions, including Gaussian functions. For each type of prediction, the input variables can be either categorical or continuous; different prediction methods are more effective, depending on the type of input variables used.

Popular methods for assessing the goodness of a predictor include linear correlation, Cohen's kappa, and A' (the area under the receiver-operating curve – e.g., Bradley, 1997). Percent accuracy is generally not preferred for classification, as values of accuracy are highly dependent on the base rates of different classes (and hence, a very high accuracy can in some cases be achieved by a classifier that simply always predicts the majority class). When computing the goodness of a predictor, it is important to account for nonindependence of different observations involving the same student – to achieve this goal, EDM researchers often apply meta-analytical methods that can account for partial nonindependence, such as Strube's (1985) Adjusted Z, or select overly conservative estimators that assume complete nonindependence.

Clustering

In clustering, the goal is to find data points that naturally group together, splitting the full data set into a set of

clusters. Clustering is particularly useful in cases where the most common categories within the data set are not known in advance. If a set of clusters is optimal, within a category, each data point in general will be more similar to the other data points in that cluster than data points in other clusters. Clusters can be created at several different possible grain sizes: for example, schools could be clustered together (to investigate similarities and differences between schools), students could be clustered together (to investigate similarities and differences between students), or student actions could be clustered together (to investigate patterns of behavior) (Amershi and Conati, 2006; Beal *et al.*, 2006).

Clustering algorithms can either start with no prior hypotheses about clusters in the data (such as the k-means algorithm with randomized restart), or start from a specific hypothesis, possibly generated in prior research with a different data set (using the expectation-maximization algorithm to iterate toward a cluster hypothesis for the new data set). A clustering algorithm can postulate that each data point must belong to exactly one cluster (such as in the k-means algorithm), or can postulate that some points may belong to more than one cluster or to no clusters (such as in Gaussian mixture models).

The goodness of a set of clusters is usually assessed with reference to how well the set of clusters fits the data, relative to how much fit might be expected solely by chance given the number of clusters, using statistical metrics such as the Bayesian information criterion.

Relationship Mining

In relationship mining, the goal is to discover relationships between variables, in a data set with a large number of variables. This may take the form of attempting to find out which variables are most strongly associated with a single variable of particular interest, or may take the form of attempting to discover which relationships between any two variables are strongest.

Broadly, there are four types of relationship mining: association rule mining, correlation mining, sequential pattern mining, and causal data mining. In association rule mining, the goal is to find if-then rules of the form that if some set of variable values is found, another variable will generally have a specific value. For example, a rule might be found of the form {student is frustrated, student has stronger goal of learning than goal of performance} \rightarrow {student frequently asks for help}. In correlation mining, the goal is to find (positive or negative) linear correlations between variables. In sequential pattern mining, the goal is to find temporal associations between events – for example, to determine what path of student behaviors leads to an eventual learning event of interest. In causal data mining, the goal is to find whether one event (or observed construct) was the cause of another event

(or observed construct), either by analyzing the covariance of the two events (e.g., TETRAD – Scheines *et al.*, 1994) or by using information about how one of the events was triggered. For example, if a pedagogical event is randomly chosen using automated experimentation (Mostow, 2008), and frequently leads to a positive learning outcome, a causal relationship can be inferred.

Relationships found through relationship mining must satisfy two criteria: statistical significance, and interestingness. Statistical significance is generally assessed through standard statistical tests, such as *F*-tests. Because large numbers of tests are conducted, it is necessary to control for finding relationships through chance. One method for doing this is to use *post hoc* statistical methods or adjustments which control for the number of tests conducted, such as the Bonferroni adjustment. This method can increase confidence that an individual relationship found was not likely to be due to chance. An alternate method is to assess the overall probability of the pattern of results found, using Monte Carlo methods. This method assesses how likely it is that the overall pattern of results arose due to chance.

The interestingness of each finding is assessed in order to reduce the set of rules/correlations/causal relationships communicated to the data miner. In very large data sets, hundreds of thousands of significant relationships may be found. Interestingness measures attempt to determine which findings are the most distinctive and well supported by the data, in some cases also attempting to prune overly similar findings. There are a wide variety of interestingness measures, including support, confidence, conviction, lift, leverage, coverage, correlation, and cosine. Some investigations have suggested that lift and cosine may be particularly relevant within educational data (Merceron and Yacef, 2008).

Discovery with Models

In discovery with a model, a model of a phenomenon is developed through prediction, clustering, or, in some cases, knowledge engineering (within knowledge engineering, the model is developed using human reasoning rather than automated methods). This model is then used as a component in another analysis, such as prediction or relationship mining.

In the prediction case, the created model's predictions are used as predictor variables in predicting a new variable. For instance, analyses of complex constructs, such as gaming the system within online learning, have generally depended on assessments of the probability that the student knows the current knowledge component being learned (Baker *et al.*, 2008b; Walonoski and Heffernan, 2006). These assessments of student knowledge have in turn depended on models of the knowledge components in a domain,

generally expressed as a mapping between exercises within the learning software and knowledge components.

In the relationship mining case, the relationships between the created model's predictions and additional variables are studied. This can enable a researcher to study the relationship between a complex latent construct and a wide variety of observable constructs.

Often, discovery with models leverages the validated generalization of a prediction model across contexts. For instance, Baker (2007) used predictions of gaming the system across a full year of educational software data to study whether state or trait factors were better predictors of how much a student would game the system. Generalization in this fashion relies upon appropriate validation that the model accurately generalizes across contexts.

Distillation of Data for Human Judgment

Another area of interest within EDM is the distillation of data for human judgment. In some cases, human beings can make inferences about data, when it is presented appropriately, that are beyond the immediate scope of fully automated data mining methods. The methods in this area of EDM are information visualization methods – however, the visualizations most commonly used within EDM are often different than those most often used for other information visualization problems (Kay *et al.*, 2006; Hershkovitz and Nachmias, 2008), owing to the specific structure, and the meaning embedded within that structure, often present in educational data.

Data are distilled for human judgment in EDM for two key purposes: identification and classification. When data are distilled for identification, data are displayed in ways that enable a human being to easily identify well-known patterns that are nonetheless difficult to formally express. For example, one classic EDM visualization is the learning curve, which displays the number of opportunities to practice a skill on the x -axis, and displays performance (such as percent correct or time taken to respond) on the y -axis. A curve with a smooth downward progression that is steep at first and gentler later indicates a well-specified knowledge component model. A sudden spike upward, by contrast, indicates that more than one knowledge component is included in the model (Corbett and Anderson, 1995).

Alternately, data may be distilled for human labeling, to support the later development of a prediction model. In this case, subsections of a data set are displayed in visual or text format, and labeled by human coders. These labels are then generally used as the basis for the development of a predictor. This approach has been shown to speed the development of prediction models of complex phenomena such as gaming the system by around 40 times, relative to prior approaches for collecting the necessary data (Baker and de Carvalho, 2008).

Main Applications

There have been a wide number of applications of EDM, as reflected throughout this article. In this section, four areas of application that have received particular attention within the field are discussed.

One key area of application is in improving student models, models that provide detailed information about a student's characteristics or states, such as knowledge, motivation, meta-cognition, and attitudes. Modeling the individual differences between students, in order to enable software to respond to those individual differences, is a key theme in educational software research. In the last few years, EDM methods have enabled considerable expansion in the sophistication of student models. In particular, EDM methods have enabled researchers to make higher level inferences about students' behavior, such as when a student is gaming the system, when a student has slipped (making an error despite knowing a skill), and when a student is engaging in self-explanation (Shih *et al.*, 2008). These richer student models have been useful in two fashions. First, these models have increased our ability to predict student knowledge and future performance – incorporating models of guessing and slipping into predictions of student's future performance has increased the accuracy of these predictions by up to 48% (Baker *et al.*, 2008a). Second, these models have enabled researchers to study what factors lead students to make specific choices in a learning setting, a type of scientific discovery with models discussed below.

A second key area of application is in discovering or improving models of the knowledge structure of the domain. In EDM, methods have been created for rapidly discovering accurate domain models directly from data. These methods have generally combined psychometric modeling frameworks with advanced space-searching algorithms, and are generally posed as prediction problems for the purpose of model discovery (e.g., attempting to predict whether individual actions will be correct or incorrect, using different domain models, is one common method for developing these models). Barnes *et al.* (2005) have proposed algorithms for automatically discovering a Q-matrix from data. Cen *et al.* (2006) proposed algorithms for using codified expert knowledge about differences between items to drive automated search for item response theory (IRT) models. Pavlik *et al.* (2008) has proposed algorithms for finding partial order knowledge structure models (Desmarais *et al.*, 1996), by looking at the covariation of individual items.

A third key area of application is in studying the pedagogical support provided by learning software. Modern educational software gives a variety of types of pedagogical support to students. Discovering which pedagogical support is most effective has been a key area of interest for educational data miners. Learning decomposition

(Beck and Mostow, 2008), a type of relationship mining, fits exponential learning curves to performance data, relating student success to the amount of each type of pedagogical support a student has received (with a weight for each type of support). The weights indicate how effective each type of pedagogical support is for improving learning. An illustrative example is given in the next section.

A fourth key area of application of EDM is for scientific discovery about learning and learners. This takes on several forms. Applying EDM to answer questions in any of the three areas previously discussed (e.g., student models, domain models, and pedagogical support) can have broader scientific benefits; for example, the study of pedagogical support may have the long-term potential to enrich theories of scaffolding. Beyond just these three areas, however, there have been many analyses aimed directly toward scientific discovery. Discovery with models is a key method for scientific discovery via EDM. Research on studying whether state or trait factors were better predictors of how much a student would game the system (Baker, 2007) is a prominent example of this approach within EDM research. Learning decomposition methods are another prominent method for conducting scientific discovery about learning and learners.

Illustrative Example

In this section, a brief case study is discussed, as a concrete, best practices example of how the EDM method of learning decomposition (a type of relationship mining) was used to determine the relative efficacy of different types of learning material presented to students.

In Beck and Mostow (2008), data were obtained from 346 American elementary school students reading 6.9 million words, over the course of a year, while using intelligent tutor software that teaches reading. These words were presented in the form of stories, and students and the software took turns choosing stories (the software's choice of stories was based on the student's approximate grade reading level). Beck and Mostow were interested in determining whether rereading a story (a popular option for children) is more or less effective at promoting word learning than encountering the same word in a different story. They were also interested in whether there would be individual differences, such that some students would benefit from a different pattern of practice than others.

Beck and Mostow obtained data for each student's performance in reading each story within the software. Reading time was used as a continuous measure of word knowledge; misreading and help-requests were also taken into account, reading opportunities where these behaviors occurred were assigned a time of 3.0 s (99.9% of word reads were faster than 3.0). An exponential model of practice was set up, relating response time to the function:

$$\text{time} = A \times e^{-b(W - \tau_1 + \tau_2)}.$$

In this equation, parameter A represents student performance on the first opportunity to read a given word, parameter b represents the overall speed of learning, e is 2.718, and τ_1 and τ_2 represent the number of times the word is read, within two different types of practice. In this case, τ_1 was defined as the number of times the word was read when rereading a story and τ_2 was defined as the number of times the word was read when reading a story for the first time. W is the relative speed gain associated with the two types of practice. If W equals 1, the two types of practice are considered to be equally effective; if W is above 1, opportunities of type τ_1 are more effective than opportunities of type τ_2 (and the reverse holds true if W is below 1).

Across the population of students, the median value of W for rereading obtained by Beck and Mostow was 0.49, suggesting that rereading a story leads to approximately half as much learning as reading a new story. Of the 346 students, 95 had a W parameter statistically significantly under 1, whereas only seven students had a W parameter value statistically significantly over 1, a statistically significant result across the entire class.

Beck and Mostow next used the values of W from the model in a subsequent logistic regression analysis (an example of discovery with models). In this analysis, the learning decomposition model was used to split the population into students who benefited from rereading and students who did not benefit from rereading, and a variety of explanatory variables were tested to see if they explained which students benefited from rereading. This analysis determined that students with overall low reading speed who were receiving special needs learning support actually benefited from rereading.

Glossary

Axiom – A proposition that is not susceptible to proof or disproof; its truth is assumed to be self-evident.

Introduction

The Process of Decision Making

One of the most common activities of human beings is that of decision making. Every person is constantly deciding on a wide variety of different subjects. There are easy as well as difficult decisions; there are important and irrelevant decisions; one must face personal and professional decisions. In the end, we all know, from our particular experience, that there are good and bad decisions, so a natural question arises. Are there any rules or procedures for decision making which guarantee that the final result is a good decision?

A vast amount of effort has been devoted to explore this subject. Psychologists have studied how decision makers work under different conditions. From a philosophical perspective, even the existence of such a thing as a good decision has been questioned. The logical approach has contributed to the understanding of the decision-making process. Mathematics, including statistics, has played a major role in providing a formal structure for the process and defining criteria for optimality.

Under the heading of decision theory, the literature offers an account of the ways people actually make decisions and a discussion on the mechanisms underlying this behavior. This is called a descriptive decision theory. On the other hand, we can also find discussions about the principles to consider when making rational decisions. In this case, we have a normative decision theory.

In this article, we are concerned with a normative decision theory. We discuss the solution of a general class of decision problems and, briefly but not less importantly, comment on the relationship between decision theory and statistical inference.

Decision Problems

A decision problem can be defined as a situation where a person or a group of people (the decision maker) must select one and only one element (an action) from a given

set $A = \{a_1, a_2, \dots, a_k\}$. The idea is to choose the best action, and thus the subjective nature of the solution arises naturally – the best action must be such for the specific decision maker. For this purpose, every action in A is judged in terms of the consequence it produces. Therefore, another component of the problem is the set of consequences $C = \{c_1, c_2, \dots, c_k\}$ where c_i stands for the consequence from action a_i . If, for every action, the corresponding consequence is completely known and occurs every time the action is selected, then we have a decision problem without uncertainty.

Under these circumstances, choosing an action is equivalent to choosing a consequence and the best action will be that leading to the best or most preferable consequence. Thus, the decision maker must define the set of actions A , the set of consequences C , and must also express her personal subjective preferences among the different elements of C . Once this structure is defined, the problem is solved by choosing the action whose consequence is the most preferable. This seems to be a rather simple exercise; however, the importance of a careful definition of the problem cannot be overestimated. The set A must include all available actions, and these must represent actual alternative options.

Concerning the principles we referred to in the section titled ‘The process of decision making’, in the case of a decision without uncertainty, these are implicit and apply to the decision maker’s preferences. They assume all actions to be comparable in terms of preferences and the preference relation to be transitive. If the structure of the problem is not well-defined or the axioms (coherence principles) are not fulfilled, the decision maker will solve (if at all) a wrong problem.

If preferences are expressed in terms of a numerical score u such that, for every pair (i, j) , c_i is less preferable than c_j if and only if $u(c_i) < u(c_j)$, then the problem reduces to maximizing the function u over C . The score u is called the utility function and the solution is any action that maximizes the decision maker’s subjective utility. Sometimes it is easier to use a loss function to represent preferences. If l is a loss function, then c_i is less preferable than c_j if and only if $l(c_i) > l(c_j)$. In this case, the best action minimizes the decision maker’s subjective loss. As long as both functions, loss and utility, describe the same preferences, the optimal decision remains the same.

Decision problems without uncertainty are conceptually simple. Nevertheless, their solution can be difficult in practice. In particular, translation of preferences into a

numerical score is not easy. However, the utility function is just a numerical representation of the preferences and thus these technical problems are usually due to the difficulties associated with the elicitation of preferences.

Recalling the question whether there are any rules or procedures for decision making which guarantee that the final result is a good decision, we can now say that, in the case of decision problems without uncertainty, if the problem is properly structured, the utility function really reflects the decision maker's preferences, and these preferences obey the coherence principles, the answer is yes.

Unfortunately, real-world decision problems are usually more complex than those without uncertainty. It often happens that once an action has been chosen, there is a set of possible consequences associated with it. Among them, one and only one will take place depending upon the occurrence of some uncertain event. The structure of a decision problem under uncertainty is described in the section titled 'Definition of a decision problem'.

Historical Background and Related Fields

Ideas related to decision theory can be traced back to at least the eighteenth century. However, most of the formal developments emerged during the past 80 years and many disciplines have contributed to the methods of decision making. The case without uncertainty belongs to the domain of optimization and operations research. Game theory provided the basic framework for the case under uncertainty. Modern economic theory too deals with interesting decisions, such as the choice of an investment portfolio. In fact, this problem is the origin of an entire field known as financial economics.

The relationship between statistics and decision theory deserves a special mention. Statistics can contribute to the solution of decision problems under uncertainty by means of methods which allow the decision maker to describe her own uncertainty. The result is known as statistical decision theory, and different approaches to statistical inference have led to different statistical decision theories. Conversely, any situation where a statistical inference is required can be seen as a decision problem under uncertainty (an inference is just an assertion regarding the phenomenon of interest and is chosen among several alternatives). From this perspective, a theory of statistical inference can be developed on the grounds of a specific decision theory. The most outstanding example is Bayesian statistics, a statistical theory built upon the axiomatic decision theory described in the section titled 'Axiomatic decision theory'. Bayesian inference, as a theoretical discipline, and Bayesian methods, as a set of tools for inference in practice, have been growing very rapidly in recent years.

Decision theory is an interdisciplinary field with many relevant contributions published in economics, mathematics,

psychology, and statistics, among other areas. The basic concepts in axiomatic decision theory were mainly developed from the 1930s to the 1970s and now appear in a number of Bayesian statistics texts.

Decisions in Education

Decisions are omnipresent in the field of education. A specific syllabus must be chosen, among different alternatives, for each course. The admissions committee must decide whether or not an applicant should be accepted as a student of the program. As part of the grading process, for every exam, a cutoff value must be selected to decide whether a student fails. On the other hand, students face a decision problem when they choose a career; every time they select an elective course they are making a decision; and when a student chooses an answer in a multiple-response test, she is also deciding among a set of alternative options. These are only a few examples of decision problems in education.

For a long time, these problems were faced without any decision-theoretical backing. However, current research in education, specifically on test design, involves decision theory as a basic resource. As discussed by van der Linden (1991), this process is related to a change in the approach to design. Formerly, a test was considered as a measurement tool and research on tests was directed to explore the relation among the observed measurement and the attribute to be measured. More recently, it has been argued that the measurement is relevant insofar as it is useful to make decisions about the examinee. Therefore, an appropriate design must take into account the specific decision problem to be addressed. For examples of this idea we refer the reader to Novick and Lindley (1978), where some particular utility functions are used to identify cutoff scores; Sawyer (1996), who uses decision theory to validate course-placement tests; and Vos (1999), where optimal sequential mastery tests are formulated using decision-theoretical arguments.

Decision Theory

Definition of a Decision Problem

A decision problem under uncertainty is defined by the following elements:

1. $A = \{a_1, a_2, \dots, a_k\}$,
2. $E = \{E_{11}, E_{12}, \dots, E_{1m_1}; E_{22}, E_{21}, \dots, E_{2m_2}; \dots; E_{k1}, E_{k2}, \dots, E_{km_k}\}$, and
3. $C = \{c_{11}, c_{12}, \dots, c_{1m_1}; c_{22}, c_{21}, \dots, c_{2m_2}; \dots; c_{k1}, c_{k2}, \dots, c_{km_k}\}$.

Here, A is an exhaustive and exclusive set of actions; E is the set of uncertain events where, for every action a_i , the collection of events $E_i = \{E_{i1}, E_{i2}, \dots, E_{im_i}\}$ is assumed to be a partition of the certain event Ω . Finally, C is the set of

consequences and is such that, to each pair (a_i, E_{ij}) , there corresponds a consequence c_{ij} . Both the space of actions and the set of uncertain events may contain an infinite number of elements.

In order to solve this problem, the simple optimality principle used in the section titled 'Decision problems', no longer applies. We cannot substitute the choice of an action by the choice of a consequence. In fact, in this new setting, once the decision maker chooses a_i , what she gets is the result of a lottery whose possible prizes are $\{u(c_{i1}), \dots, u(c_{imi})\}$ where $u(c_{ij})$ occurs with probability $p_{ij} = P(E_{ij})$ and, for each i , $p_{i1} + p_{i2} + \dots + p_{imi} = 1$. Here, there is no obvious way to transfer a utility score to the action a_i from the corresponding lottery. In fact, every method devised to solve a problem of this kind relies on a specific proposal of how to carry this out. Moreover, since the event E_{ij} is uncertain for the decision maker, the probability p_{ij} is a measure of her personal beliefs about the occurrence of E_{ij} . Thus, both utilities and probabilities are subjective.

A number of methods have been proposed to solve decision problems under uncertainty; all of them replace the original problem with another which, in a way, does not involve any uncertainty (see the next section).

Example

A graduate studies committee must evaluate every application to a PhD program and decide whether the corresponding candidate can be admitted. In a simplified version, only two actions are considered. Thus $A = \{a_1, a_2\}$, where a_1 = admit the candidate, a_2 = reject the candidate. The consequences of each of these actions are uncertain. Rejection of a candidate would be appropriate if this action prevents admission of a bad student. On the other hand, it would be a mistake to reject a good student. If the set of uncertain events is defined as $E = \{E_1, E_2\}$, with E_1 = candidate's performance is good, E_2 = candidate's performance is poor, then the consequences are given by $C = \{c_{11}, c_{12}, c_{21}, c_{22}\}$ where c_{ij} is the consequence obtained if the action a_i is chosen and the uncertain event E_j occurs. Here, c_{11} and c_{22} represent good outcomes whereas c_{12} and c_{21} are mistakes. A reasonable utility function describing these preferences must be such that $u(c_{ii}) > u(c_{ij})$ for $i, j = 1, 2$. This problem has the structure described by Figure 1.

Intuitive Solutions to a Decision Problem

Here, we review two popular methods used to solve a decision problem under uncertainty. As many others, each of them proceeds in a two-step fashion. First, for every action, a utility score is derived from the corresponding lottery. In the second step, actions are compared as they would be in a problem without uncertainty, so the best action is chosen as that maximizing the derived utility.

Figure 1 A decision tree: the square represents a decision node while circles represent uncertain nodes.

Minimax

For each action a_i , this method looks at the worst possible consequence and then acts as if this consequence will occur for sure. In other words, Minimax assigns the utility $u_M(a_i) = \min_j u(c_{ij})$ and this new utility is then maximized over the space of actions, so that the best action, denoted by a^* , is such that $a^* = \max_i \min_j u(c_{ij})$. The method is named after this last expression: Maximin, if we work in terms of utilities or Minimax if a loss function is used. This procedure completely ignores the probabilities that the decision maker has assigned to the events in E_i . In some sense, this is a pessimistic approach to decision making and often yields what is known as opportunity loss.

Maximum expected utility

This method assigns, to each action a_i , the weighted average of the utilities assigned to the corresponding consequences, the weights being the respective probabilities, that is, $u_E(a_i) = u(c_{i1}) p_{i1} + u(c_{i2}) p_{i2} + \dots + u(c_{imi}) p_{imi}$. This expected utility is then maximized over the space of actions, so that the best action, denoted by a^* , is such that $a^* = \max_i u_E(a_i)$. This approach to decision making takes into account all the information and is the only one that is consistent with the axiomatic theory described in the next section.

Example (ctd.)

Let $p_1 = P(E_1)$ and $p_2 = P(E_2)$. In this case, the expected utilities are computed as $u_E(a_1) = u(c_{11}) p_1 + u(c_{12}) p_2$ and $u_E(a_2) = u(c_{21}) p_1 + u(c_{22}) p_2$, and the action leading to the larger of these two quantities is chosen. For the sake of simplicity, let us consider the case where the preferences are described by means of a loss function. Moreover, let us assume that consequences associated with successes are assigned a zero loss so that $l(c_{11}) = l(c_{22}) = 0$ (with $l(c_{ij}) > 0$; $i \neq j$). In this setting,

$I_E(a_1) = I(c_{12}) p_2$, $I_E(a_2) = I(c_{21}) p_1$ and then a_1 is chosen as the optimal action if, and only if, $I(c_{12}) p_2 < I(c_{21}) p_1$ or, equivalently, $p_1/p_2 > I(c_{12})/I(c_{21})$. Here, the cutoff value depends on the relative importance of c_{12} and c_{21} . Note that, even if $p_1 < p_2$, a_1 will still be chosen as the best action if $p_1 > (I(c_{12})/I(c_{21})) p_2$.

Axiomatic Decision Theory

Coherence axioms can be formulated in several different ways. One of the most intuitive discussions concerning the axiomatic basis for decision theory appears in Lindley (1972). For a more technical version, the reader is referred to Bernardo and Smith (1994).

Let us represent an action a by $a = \{c_1 | E_1, \dots, c_m | E_m\}$, thus indicating that an action is just a lottery where the decision maker gets the consequence c_j whenever the event E_j occurs. Then, it is clear that any consequence c is a particular case of an action since c is equivalent to $\{c | \Omega\}$, where Ω is the certain event.

1. *Axiom 1* (comparability). For every pair of actions a_1 and a_2 in \mathcal{A} , one and only one of the following conditions holds:

- a_1 is less preferable than a_2 (denoted $a_1 < a_2$)
- a_1 is more preferable than a_2 (denoted $a_1 > a_2$)
- a_1 and a_2 are equally preferable (denoted $a_1 \sim a_2$).

Moreover, it is possible to find two consequences c^* and c_* such that $c^* > c_*$ and $c_* \leq c \leq c^*$ for any consequence c ($a_1 \leq a_2$ means a_1 is not more preferable than a_2 ; $a_1 \geq a_2$ is similarly defined).

Discussion. The comparability of actions implies both the comparability of consequences and the comparability of events. Denote by \bar{E} the complement of the event E and let $a_1 = \{c^* | E_1, c_* | \bar{E}_1\}$ and $a_2 = \{c^* | E_2, c_* | \bar{E}_2\}$. Then comparing a_1 with a_2 is equivalent to comparing the likelihoods of the events E_1 and E_2 : a_1 will be preferable to a_2 if and only if E_1 is more likely than E_2 .

2. *Axiom 2* (transitivity). If $a_1 > a_2$ and $a_2 > a_3$, then $a_1 > a_3$.

Discussion. This axiom assumes that the set of actions can be ordered in such a way that a search for the most preferable element makes sense.

3. *Axiom 3* (substitutability and dominance). If $a_1 > a_2$ when the event E occurs and $a_1 > a_2$ when the event \bar{E} occurs, then $a_1 > a_2$.

Discussion. This axiom implies that, in any given action $a = \{c_1 | E_1, \dots, c_m | E_m\}$, a consequence c_j can be replaced by any action which is equivalent to c_j . This axiom also implies that, given two actions $a_1 = \{c_{11} | E_1, \dots, c_{1m} | E_m\}$ and $a_2 = \{c_{21} | E_1, \dots, c_{2m} | E_m\}$, if $c_{1j} \geq c_{2j}$ for all j , then $a_1 \geq a_2$. Moreover, if $c_{1j} > c_{2j}$ for some j , then $a_1 > a_2$.

4. *Axiom 4* (reference events). The decision maker can conceive of a procedure to generate a random point in the unit square such that, given two regions R_1 and R_2 in the unit square, the event that the random point is contained in R_1 is regarded as more likely than the event that the random point is contained in R_2 if, and only if, the area of R_1 is larger than the area of R_2 .

Discussion. This axiom defines a unit of measurement which can be used to describe the decision maker's uncertainty concerning the occurrence of the various events which are relevant for the decision problem.

Axioms 1–3 are qualitative. They establish the rules that comparison of actions must obey. Axiom 4 is of a quantitative nature and allows the decision maker to measure her degree of belief concerning uncertain events in terms of probability.

The axioms imply a three-step procedure to choose among actions. First, all preferences between consequences must be quantified in terms of a numerical utility (or, alternatively, a loss) function. Second, the uncertainty regarding any event affecting the consequences of an action must be quantified in terms of probability. Finally, the decision maker's preferences about any pair of alternative actions must be described in units of expected utility and hence the best decision will be to choose the action that maximizes such expected utility.

In brief, the main idea behind this formulation is this: if the coherence axioms are acceptable for a decision maker, then she has no other option but to use the maximum expected utility criterion to choose among actions. Any other method leads to the same optimal decisions or conflicts with the axioms. Stating the axioms explicitly allows anyone to evaluate if she is willing to act as a coherent decision maker defined in this particular way. In addition, if the axioms are adopted, the existence of a probability function for the uncertain events, and a utility function for the consequences, is no longer an assumption. It is a fact, following from the axioms themselves.

This is a subjective method since the utility and probability functions must describe the preferences and beliefs of the specific decision maker. Interestingly, the subjective nature of the utility function has not been a matter of controversy. On the other hand, the idea of subjective probabilities led to a lively debate in the early years and even now appears as a relevant issue in some applications (see Schneider (2002), for an example).

When the decision maker is faced with new information concerning the uncertain events, her beliefs must be revised in order to obtain an updated (posterior) probability measure describing all the available knowledge (which includes the original, prior beliefs as well as the new information). Another important consequence of the axioms is that this updating must be consistent with Bayes' rule.

When dealing with decisions under uncertainty, one cannot guarantee that the optimal action is a good decision in the sense that it will necessarily lead to the best possible consequence. Apart from guaranteeing compliance with the coherence axioms, the maximum expected utility method only leads to the action whose expected consequence is the most preferable.

Example (ctd.)

To improve the results of the admission process to the PhD program, the graduate studies committee can ask the candidates to take a selection exam. The corresponding grade of the exam (X) is then used to update the probabilities $P(E_1)$ and $P(E_2)$. If the observed grade is x , then the new probabilities are defined as $P(E_1 | X=x)$ and $P(E_2 | X=x)$ and can be obtained via Bayes' formula as $P(E_i | X=x) = P(X=x | E_i) P(E_i) / P(X=x)$; $i = 1, 2$.

If these updated probabilities are used to make a decision, a_1 must be chosen if, and only if, $P(E_1 | X=x) / P(E_2 | X=x) > \ell(c_{12}) / \ell(c_{21})$. Equivalently, a_1 is the best action if $P(X=x | E_1) / P(X=x | E_2) > (p_2 / p_1)(\ell(c_{12}) / \ell(c_{21}))$. Here, statistical knowledge is useful to propose the models $P(X=x | E_1)$ and $P(X=x | E_2)$ describing how likely a grade is under each of the scenarios E_1 and E_2 . The decision is thus based on the likelihood ratio $P(X=x | E_1) / P(X=x | E_2)$. In this case, the cutoff value depends on both the ratio of the probabilities p_1 and p_2 and the relative importance of the possible mistakes. An interesting issue closely related to this problem is that of the test design. If the classification exam is properly designed, it would be reasonable to expect high grades among those candidates who later prove to be good students and lower grades among bad ones. If the classification exam works well as a screening tool, the ratio $P(X=x | E_1) / P(X=x | E_2)$ should be a nondecreasing function of x and then $P(X=x | E_1) / P(X=x | E_2)$ will be larger than $(p_2 / p_1)(\ell(c_{12}) / \ell(c_{21}))$ only if x is larger than a cutoff given by $b((p_2 / p_1)(\ell(c_{12}) / \ell(c_{21})))$ where the function b depends on how well the exam discriminates between good and bad candidates, a characteristic that can be analyzed through statistical methods. This decision rule leads to the expected result: candidates with a high grade are admitted whereas those with a low grade are rejected. The more subtle issue is related to the cutoff value. How high should a grade be for a candidate to be admitted? Under this decision-theoretical framework, it is clear that the best rule is not necessarily to admit a candidate only if she passes the exam. Depending on the combination of the prior probabilities p_2 and p_1 , losses $\ell(c_{12})$ and $\ell(c_{21})$, as well as on the function b , it might be optimal to admit some candidates who do not pass the exam or to reject some who pass the exam with a relatively low grade. This procedure proposes a solution for the choice of the cutoff value in a straightforward manner which makes it clear

what the components of the problem are and how these should be taken into account.

Some Applications

The literature offers a variety of applications of decision theory in education, mostly in the field of education research. In particular, van der Linden (1991, 1997) provides a comprehensive review of applications to test theory. More recently, Vos (1999) and Vos and Glas (2000) propose a sequential decision procedure to develop adaptive mastery tests, whereas Segall (2004) applies ideas from decision theory to evaluate a new sharing item-response theory model (see also van der Linden (1998)). A common feature of these contributions (as well as many others of this type) is that the role of decision maker is played by the researcher, the instructor, or even the computer system used to administer the test.

From a different perspective, but also in the field of test design, Bernardo (1998) discusses several grading procedures for the case of multiple-choice examinations. There, the student, as the decision maker, must devise a strategy to answer each item of the examination. In this context, however, the corresponding decision problem is defined by the instructor, who determines the set of possible answers A , the set of uncertain events E , the consequences set C , and, very importantly, the utility function (the grading-score mechanism). If the student is a coherent decision maker in the sense of axiomatic decision theory, she must choose the answer maximizing her expected utility. This expectation is computed by combining the grading-score function of the test and the subjective-probability distribution describing the student's knowledge.

Bernardo shows how the utility function can be defined in order to discourage guessing. He also discusses the cases where the aim of the student is either to get the highest mark or just to pass the examination. In addition, and elaborating on an original idea by de Finetti (1965), he explores the results obtained when the student is asked not only to mark the correct option but to report her entire probability distribution over the set of possible answers for each item of the test.

Current Developments

Decision theory is an active field of research. The list of problems under current investigation include: experimental studies of individual and group behavior; use of different methods to understand human judgments and decisions; discussion of alternative normative models; and applications of the theory to a wide variety of subjects.

Specifically, alternative sets of axioms are being explored to produce a structure able to encompass the widest range of real problems; Lipman (1999) and

Dubois *et al.* (2003) are two examples of this type of investigation. Another line of research has to do with elicitation of both utilities and probabilities. Clemen and Reilly (1999) discuss the use of copulas for this purpose whereas Bleichrodt and Pinto (2000) explore a specific procedure in the context of medical decisions. In addition, for some decision problems, maximization of the expected utility can only be accomplished through numerical or simulation methods (see Bielza *et al.* (1999), for instance). Beyond the limits of the theory described in this article, there are researchers who assume that consequences might include several facets, and preferences for each one of them are described through a different utility function. This framework is known as a multi-objective decision problem and there is no generally accepted solution in such a setting (see Dyer *et al.*, 1992). Another problem whose general solution is yet to be formulated is that of group decision. If the decision maker is a committee where each member has a different utility function or a different probability distribution, how should these be combined to choose the action with the largest expected utility? Will this combination be an optimal solution in practice? Weerahandi and Zidek (1981) propose a solution for this problem; Hollenbeck *et al.* (1998) take into account the structure of the group through multilevel theory.

Concerning Bayesian statistics, the statistical ramification of decision theory, current research also includes alternative axiomatic formulations (see Karni, 2007, for a recent example), elicitation techniques (Garthwaite *et al.*, 2005), and applications in an ever-increasing number of fields. There is also a strong research effort directed toward statistical computing. Specifically, simulation techniques for the calculation of posterior distributions using Markov Chain Monte Carlo (MCMC) methods have been successfully employed over the last 15 years (Bhattacharya and Haslett, 2007, provide an example).

Glossary

Causal studies – A type of research study designed to determine whether one or more variables actually cause changes in one or more outcome variables.

Control group – The group that does not receive the intervention within a research study.

Descriptive studies – A type of research study that involves the collection of data to simply describe a phenomenon.

Internal validity – The extent to which a researcher can accurately state that the independent variable caused the changes in the outcome variable(s).

Intervention group – The group that receives the intervention within a research study.

Quasi-experimental design – A research design in which assignment to intervention or control groups is not done by random assignment.

Random assignment – A process or procedure in which participants are assigned to the intervention or control group by a random process.

Randomized experimental design – A research study in which assignment to intervention or control groups is done by random assignment.

Relational studies – A type of research study that attempts to quantify the direction and strength of a relationship between two or more variables.

The topic of research methodology has never been more relevant to education than at the current time, as the shift within education policy is the movement toward evidence-based practice. To establish what actually consists of evidence-based practice, high-quality evidence from research is a necessity. For research to be considered high quality, it is necessary that researchers adhere to certain standards and indicators of quality; these quality indicators and standards ultimately dictate certain features of research designs and methodology. In addition, statistical analyses are implicitly linked to research design, in that these procedures are intended to remove variability (e.g., error) within the system that cannot be addressed by the research design alone. In fact, an appropriate research design and process for data collection allows a researcher to take full advantage of the wide range of new statistical analyses that are available. Consequently, the design of an experiment and the selection of appropriate statistical procedures are critical in establishing evidence-based

practices. In this article, we examine (1) the evolving role of research within education, (2) the legal and professional guidelines for conducting education research, and (3) some available research designs and statistical procedures that are used to conduct education research.

The Evolution of Education Research

Historically, education research has been believed to suffer from a lack of scientific rigor. During the past decade, however, there has been an increased emphasis on developing a scientific foundation for education interventions and practices. The impetus for this increase within education was the passage of the No Child Left Behind Act (NCLB) of 2001, which codified that teachers must use evidence-based teaching practices to ensure that students receive the highest-quality instruction (see Eisenhart and Towne (2003) for a historical perspective of the evolution of the definition of scientifically based education research in NCLB).

Experimental Design and Statistical Procedure Considerations

Consideration of experimental design is critical in education research. When properly designed, an educational experiment will ensure a sufficient amount of data and the right data to properly, clearly, and efficiently answer the research question of interest. In essence, a properly designed experiment will allow the investigator to improve the precision of the answer to the examined research question. Thus, scientifically rigorous experimental designs and statistical analyses enhance the validity of the researcher's conclusions.

Quality Indicators

Numerous governmental and professional organizations have developed documents and guidelines that outline quality indicators of high-quality research to assist practitioners and researchers in developing and identifying evidence-based practices. An astute researcher will be familiar with these quality indicators and proactively consider these indicators when designing an experiment. For example, the What Works Clearinghouse, which evaluates education programs for the United States Department of

Education, developed evidence standards for reviewing group randomized controlled trial studies (Institute for Education Sciences (IES, 2008)).

Similarly, Division 16 (school psychology) of the American Psychological Association, the Society for the Study of School Psychology, and the National Association of School Psychologists sponsored a task force to develop a *Procedural and Coding Manual* for review of evidence-based programs in school psychology (Task Force on Evidence-Based Interventions in School Psychology, 2003, 2009). The manual addresses numerous issues that should be considered *a priori* by researchers, including randomized and nonrandomized designs, statistical treatment and data analysis, measurement issues, comparison groups, and appropriate unit of analysis, among others. Other organizations that developed quality indicators relating to education research include the Council for Exceptional Children (2004) and the National Research Council (2002).

Research Designs

Clearly, an in-depth discussion of the entire range of research designs and the corresponding nuances associated with each research design is beyond the scope of this article. Instead, we provide a broad overview of some common research designs and appropriate statistical procedures associated with these research designs. Research designs can be categorized in various ways; in the broadest sense, research designs can be classified into three general categories, including (1) descriptive, (2) relational, and (3) causal. The selected research design should be congruent with the research question of interest, as well as providing a match with the desired scientific rigor and the practicality of conducting the study.

Descriptive Studies

Descriptive studies are intended to collect data to simply describe a phenomenon. An example of a descriptive study within education would be determining the number of English-language learners attending school within a certain state, which could then have implications for instructional practices. Analysis of descriptive studies generally consists of the use of descriptive statistics, which allows for comparisons across people or groups. Common statistics include measures of distribution, central tendency, and variability (e.g., range and standard deviation).

Relational Studies

Relational studies attempt to quantify the direction and strength of a relationship between two or more variables.

Correlation studies are most often defined as a nonexperimental design as internal validity is weak, thereby indicating that making causal statements between cause and effect is not recommended. An example of a relational study within education would be the examination of the relationship between English-language proficiency (i.e., proficient in English vs. not proficient in English) and academic achievement. Analysis of relational data frequently includes the use of various correlation techniques (e.g., Pearson product moment correlation).

Causal Studies

Causal studies are designed to determine whether one or more variables actually cause changes in one or more outcome variables. Internal validity, which is the extent to which we can accurately state that the independent variable caused the changes in the outcome variable(s), is a critical component within causal studies. To establish internal validity (and thus a causal relationship), three criteria need to be adequately addressed. These criteria consist of:

1. temporal precedence, which is establishing that the cause (i.e., independent variable) occurs before the effect (i.e., outcome);
2. establishing that the cause and effect are related and/or covary; and
3. establishing that there are no plausible alternative explanations.

The most appropriate way to address these criteria is through the use of various research designs; the stronger the research design, the more likely it is that the researcher is able to control sources of error in their methods and results. Specific procedures for controlling this variance include: (a) randomization, (b) accounting for conditions/factors into the design as independent variables, (c) holding conditions/factors constant, and (d) statistical adjustments. Whereas (a), (b), and (c) can be controlled when structuring the research design, (d) is conducted during the analysis stage.

A variety of experimental research designs can be used within causal studies; these designs can be classified as being (1) randomized experimental, (2) quasi-experimental, or (3) single-case designs. The primary and critical difference between randomized experimental and quasi-experimental designs is the presence of random assignment for randomized experimental designs, and the presence of a control group or the use of multiple measures in quasi-experimental designs. Although single-case designs are frequently classified as quasi-experimental designs, we include them as a separate classification within this article as they can serve as an alternative to using large, aggregate group designs. The variations within each type of design are discussed in more detail below.

Randomized Experimental Design

In a randomized experiment, participants are assigned to receive the control or intervention condition by a random process. The critical component within such a design is that the assignment to a control or intervention condition is truly random; this random assignment typically allows for the strongest causal inferences (i.e., high internal validity) to be made free of extraneous assumptions. There are numerous methods of implementing random assignment; Shadish *et al.* (2002: 295) identify seven common different varieties of random assignment, including:

1. simple random assignment,
2. restricted random assignment to force equal sample sizes,
3. restricted random assignment to force unequal sample sizes,
4. batch randomization,
5. trickle process randomization,
6. adaptive randomization strategies, and
7. random assignment from matches or strata.

However, even with randomized designs, various threats to validity (e.g., differential attrition, small sample size, and lack of external validity) can still occur and need to be considered. Some of the more frequently used randomized experimental designs are described in more detail below; however, it should be noted that each of these designs can also be classified as quasi-experimental designs if random assignment is not utilized.

Control group designs

Common control group designs are the posttest-only control group design and the pretest–posttest control group design. However, because the assumption that the groups were equivalent prior to the implementation of the intervention cannot be made as a result of not using a randomized assignment process, the selection and assignment process to groups can pose a threat to the experiment's internal validity. Consequently, causal statements attributing differences in outcomes must be made with extreme caution.

In the posttest-only control group design, pretests are not administered. Instead, the intervention group (or multiple groups) and the control group are only measured on the construct of interest (e.g., test) following the implementation of the intervention. Thus, the posttest scores are used to determine the effects of the intervention. This can be represented as:

$$G_1 \ X \ O_{\text{post}}$$

$$G_2 - O_{\text{post}}$$

where G_1 is group 1 (intervention group), G_2 is group 2 (control group), X is the implemented intervention, O_{post}

is the group 1 outcome measure (i.e., posttest), and O_{post} is the group 2 posttest score.

In the pretest–posttest control group design, the intervention group (two or more groups) and control groups are administered both the pretest and the posttest. Obtaining pretest scores allows the researcher to examine the equivalency of the intervention group and the control group before the intervention was implemented. Having these pretest scores allow for a variety of different analysis procedures to be used, as the pretest scores can be used as a statistical control in the analyses. A pretest–posttest control group design can be represented as:

$$G_1 \ O_{\text{pre}} \ X \ O_{\text{post}}$$

$$G_2 \ O_{\text{pre}} - O_{\text{post}}$$

where G_1 is group 1 (intervention group), G_2 is group 2 (control group), X is the implemented intervention, O_{pre} is the pretest score, and O_{post} is the posttest score.

Factorial designs

Factorial designs are utilized when it is desirable to include two or more independent (i.e., intervention) variables in the design. Within factorial designs, a factor refers to the independent variable. In a study with two independent variables, each of which has two levels, one would have a 2×2 factorial design; altogether, there are four different groups, each of which receives a different combination of levels of factors. A posttest-only 2×2 factorial design can be represented as (with different combinations of levels of factors indicated by subscripts):

$$G_1 \ X_{1,1} \ O_{\text{post}}$$

$$G_2 \ X_{1,2} \ O_{\text{post}}$$

$$G_3 \ X_{2,1} \ O_{\text{post}}$$

$$G_4 \ X_{2,2} \ O_{\text{post}}$$

whereas a pretest–posttest 2×2 factorial design can be represented as:

$$G_1 \ O_{\text{pre}} \ X_{1,1} \ O_{\text{post}}$$

$$G_2 \ O_{\text{pre}} \ X_{1,2} \ O_{\text{post}}$$

$$G_3 \ O_{\text{pre}} \ X_{2,1} \ O_{\text{post}}$$

$$G_4 \ O_{\text{pre}} \ X_{2,2} \ O_{\text{post}}$$

Factorial designs can consist of more than two levels for each of the independent variables. For example, a 3×4 factorial design would require 12 intervention groups. Given that the number of groups can become quite large as the number of levels and factors increase, there are

a variety of designs that can be used to minimize the necessary number of groups. An incomplete factorial design allows for certain intervention combination groups to not be implemented; in this situation, it would be possible to make the excluded group a control group.

Blocked designs

Within blocked designs, blocking is the arrangement of individuals (i.e., units) into similar groups (i.e., blocks). This variable is referred to as a blocking factor, which usually is a source of variability that is not of interest in the study; thus, a blocking factor can also be considered to be a nuisance factor. A simple example of a blocking factor can be gender; a blocked pretest–posttest design in which gender is blocked (thus, the two groups are male and female) can be represented as:

$$B_1 \quad G_1 \quad O_{pre} \quad X \quad O_{post}$$

$$G_2 \quad O_{pre} - O_{post}$$

$$B_2 \quad G_1 \quad O_{pre} \quad X \quad O_{post}$$

$$G_2 \quad O_{pre} - O_{post}$$

where B_1 is the group in which gender is blocked to only include males, B_2 is the group in which gender is blocked to only include females, G_1 is subgroup 1 (intervention group; within both the male and female groups), G_2 is subgroup 2 (control group; within both the male and female groups), X is the implemented intervention, O_{pre} is the pretest score, and O_{post} is the posttest score.

Quasi-Experimental Designs

In many cases, particularly in some educational settings, random assignment is neither feasible nor possible. In this case, quasi-experimental designs can be considered. The core component in a quasi-experimental study is that the participants are not randomly assigned to conditions. Without careful use of statistical controls that account for varying degrees of pre-intervention equivalence, confounds may be present that negatively impact the validity of the results. Consequently, inferring a causal connection is not recommended; at a minimum, the researcher should stress that alternative explanations could account for the differences between the intervention and control groups.

Regression discontinuity designs

IES (2008) defines regression discontinuity designs as “designs in which participants are assigned to the intervention and the control conditions based on a cut-off score on a pre-intervention measure that typically assesses need or merit. This measure should be one that has a known functional relationship with the outcome of interest over

the range relevant for the study sample” (p. 1). The primary difference between a regression discontinuity design and a nonequivalent comparison group design is that in the former, assignment to intervention group is made based on the individual’s score on a pre-program measure. This strategy allows the researcher to target an intervention to a certain individual or group in need of the intervention without compromising internal validity.

Time-series designs

Quasi-experimental time-series designs can be one of the more powerful class of quasi-experimental designs, particularly when the design incorporates various components to strengthen the design elements (e.g., control series). These design elements include consideration of assignment to conditions, measurement considerations, the use of various comparison groups, and the scheduling of interventions (see Shadish *et al.* (2002) for an in-depth discussion of how to strengthen quasi-experimental designs).

Single-Case Research Designs

Although usually labeled a quasi-experimental time-series design, single-case research designs are described in this article as a separate form of research design (formerly termed single-subject or $N = 1$ research) that have a long and influential history in psychology and education (e.g., Kratochwill, 1978; Levin *et al.*, 2003) and can serve as an alternative to using large, aggregate group designs (Shadish and Rindskopf, 2007). Single-case research designs bear similarly to time-series design and have often been regarded as quasi-experimental because they usually do not (but could) include randomization in the experiment. In the single-case design, replication is scheduled to help rule out various threats to validity. Single-case designs can involve a single participant or group as the unit but differ from repeated measures and hierarchical linear modeling (HLM) designs because multiple observations are taken over a long period of time within a design structure of replication and/or randomization of the conditions of the experiment.

There are three major types of single-case design that incorporate replication as a design characteristic and are used in applied and clinical work: the A-B-A-B within-series design, the multiple-baseline design, and the alternating treatment design. The A-B-A-B design represents an attempt to measure a baseline (the first A), a treatment measurement (the first B), the withdrawal of treatment (the second A), and the reintroduction of treatment (the second B) and involves replication of the treatment within one or more series on an individual participant or group. The A-B-A-B format is regarded as a within-series design structure since the intervention is replicated within the repeated assessment across the four phases. Causal inferences are drawn from the replication at three

points in time, going from A to B, from B to A, and from A to B. The multiple-baseline design involves replication across participants, settings, or behaviors in a single participant or groups. In this design, the treatment is staggered and introduced sequentially in a time-lagged fashion usually on at least three separate series, although more add credibility to causal inference. This format involves a combined-series design structure in that a within-series (i.e., A to B) and replication across series/units (participants, settings, and behavior) lagged in time is scheduled. In the alternating treatment design, following a baseline phase, the treatments are alternated in rapid succession (compared to the ABAB design which has more within phase observations or measurements) allowing a comparison of the treatment to baseline or an alternative treatment over repeated observations (e.g., ABABABABAB and ABCBCBCBC). The alternating treatment phases can be counterbalanced or randomized.

In each of these designs the researcher must attend to various features of the data, including mean changes among phases, trend, variability, and autocorrelation in the data. In general, these designs can be improved by structuring various forms of randomization into the design structure, thereby improving the internal validity of the design and

allowing certain forms of statistical analysis, such as randomization tests, to be conducted (see Kratochwill and Levin, in press).

Statistical Analysis Considerations Within Causal Studies

Selecting the appropriate research design, assigning individuals to intervention and control groups, and collecting appropriate data are necessary, but not sufficient, steps to answering a research question. Instead, these procedures are prerequisites for selecting the appropriate method of statistical analysis. There are a tremendous number of possible statistical techniques that can be used to analyze data, including parametric and nonparametric techniques, *t*-tests, analysis of variance (ANOVA), analysis of covariance (ANCOVA), regression analysis, and numerous multivariate methods; **Figures 1** and **2** provide an overview of many of these techniques. Erceg-Hurn and Mirosevich (2008) also provide a concise overview of how to select modern and robust statistical methods.

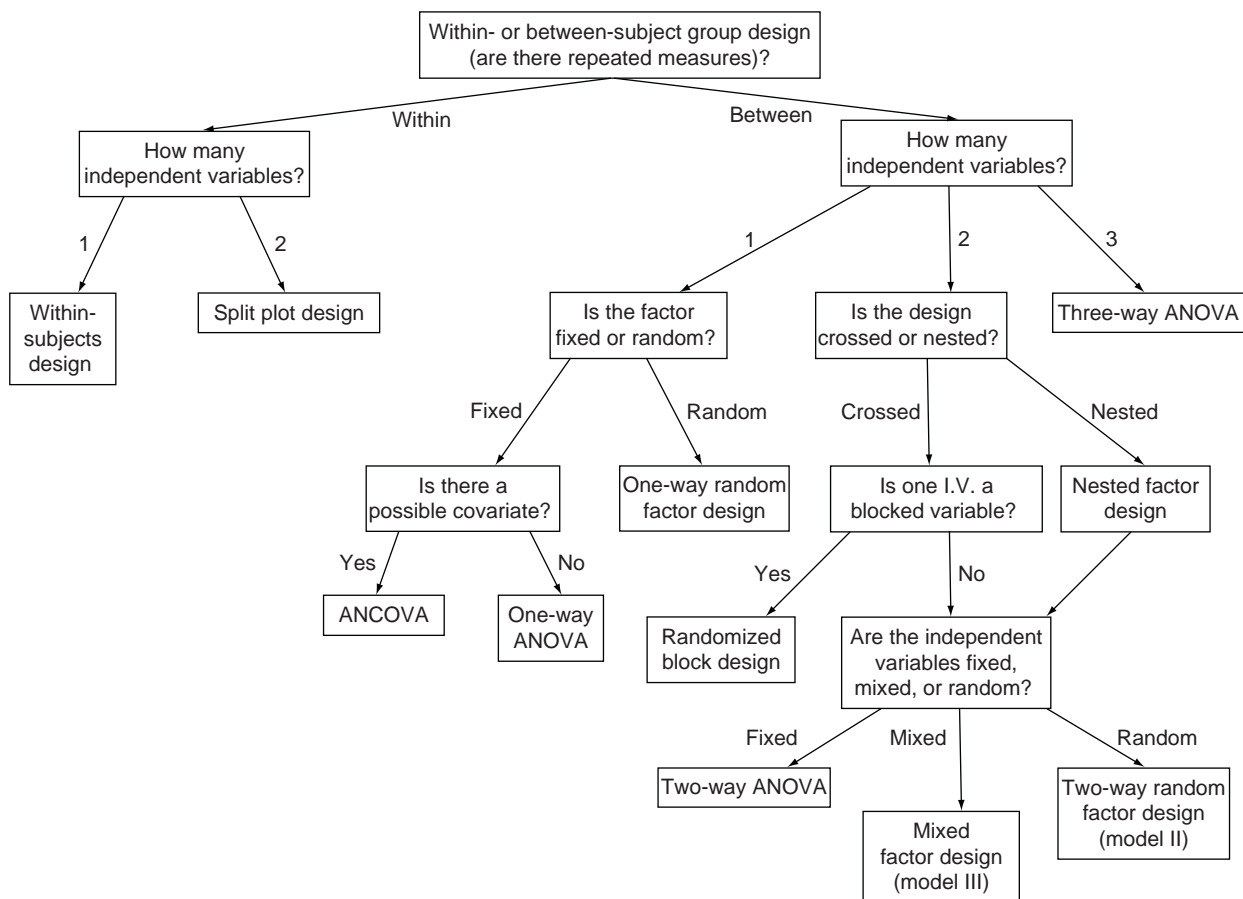

Figure 1 Group design variations and example analysis applications.

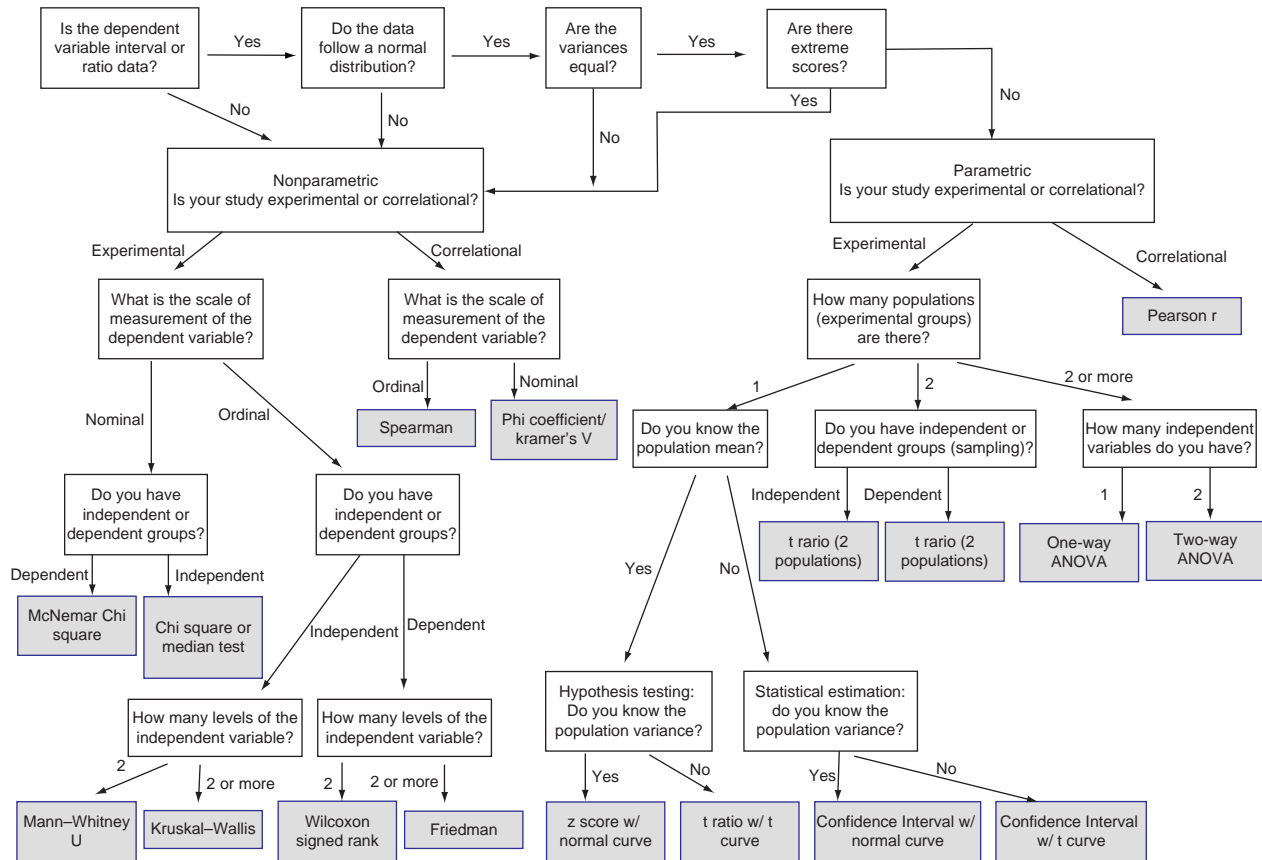

Figure 2 Selection of statistical analysis procedures.

To illustrate the link between research design and statistics, we provide an overview of a research study (Sinclair *et al.*, 1998) that was identified by the What Works Clearinghouse as meeting evidence standards for demonstrating the effectiveness of a high school dropout prevention program. Identified as a randomized controlled trial (using a posttest only group design), participants were randomly assigned using a stratified selection procedure to the intervention group and control group. No pretest measures were obtained, whereas three outcome (i.e., posttest) measures (i.e., participation in school, school performance, and identification with school) were collected. Thus, the design can be represented as:

$$G_1 \times O_{1,2,3}$$

$$G_2 - O_{1,2,3}$$

where G_1 represents the intervention group, G_2 represents the control group, X represents the intervention, O_1 represents posttest measure 1, O_2 represents posttest measure 2, and O_3 represents posttest measure 3.

Analyses, including t -tests and chi-square tests of independence, examined differences between intervention and control groups. Results indicated a significant difference between intervention and control groups on the measure

of participation in school, $\chi^2(1) = 6.87, p < 0.05$. On one of the measures (i.e., class credits) of school performance, the students who received the intervention earned significantly more credits than the students assigned to the control group, $t(90) = 4.01, p < 0.05$. On the third posttest measure (i.e., identification with school), there were no significant differences between intervention and control students.

Summary

The expectations for what constitutes acceptable education practices have undergone a significant and meaningful transformation during the past decade. Whereas past practices were based on a belief in doing what we think should work, current practices and policies are guided by the belief in doing what scientifically sound research has clearly demonstrated to be effective practices. This mandate for using evidence-based practices, which became the expectation as a result of the passage of NCLB in 2001, requires the application of strong research methodology to determine evidence-based practices.

Although the federal government and various professional organizations have clearly articulated a preference

for using randomized experimental designs to determine evidence-based practices, it would be erroneous to automatically presume that such designs are the best of all possible designs. Although randomized experimental designs allow for the strongest causal inferences to be made free of extraneous assumptions, using such a design does not guarantee that various threats to the study's validity are not present. Instead, each of the research designs should be recognized to have relative strengths and weaknesses, with the results being interpreted with these in mind.

To continue establishing evidence-based education practices, there clearly is a need for additional scientifically sound research to be conducted. Critical to this agenda is the use of the appropriate research designs and statistical procedures to answer the question of interest. Although randomized experimental designs have implicitly and explicitly been identified by some to be the gold standard of research designs, there is a growing recognition that the appropriate use of alternate research designs, especially when combined with more advanced statistical techniques, can contribute to the identification of evidence-based practices.

Discrete Probability Distributions

S Sinharay, ETS, Princeton, NJ, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Estimate – A function of sample data used for approximating a population parameter.

Moment – The n th moment about a value c of a random variable that has a probability density function $f(x)$ is $\mu'_n = \int_{-\infty}^{\infty} (x - c)^n f(x) dx$.

A discrete random variable (denoted X) is one that can take one of an enumerable or countably infinite set of values x_i , $i = 1, 2, \dots$, each with a specific probability p_i so that the probabilities over all the values add up to 1 (i.e., $\sum_i p_i = 1$). The function that specifies the probabilities for the possible values is defined as the probability mass function (PMF). The cumulative distribution function (CDF) of a discrete distribution is a step function. Discrete random variables occur naturally in statistics. One reason of this is rounding of continuous variables (e.g., height, a continuous variable, is measured in inches). Holland (1979) commented that the world is full of discrete data. Hence, several types of discrete random variables have been suggested in the literature. There also exist several statistical methods specifically designed to handle discrete data – see, for example, Bishop *et al.* (1975).

In the following sections, several discrete distributions are discussed. For each distribution, its genesis, PMF, moments, estimation of the moments, methods to generate values of a random variable following that distribution, and relationships to other distributions (if any) are discussed.

Bernoulli Distribution

The Bernoulli distribution is the most basic discrete distribution. A variable that follows the distribution can take one of two possible values, 1 (usually called a success) or 0 (failure), where the probability of success is p , $0 < p < 1$. An example of a Bernoulli random variable (that is a variable that follows the Bernoulli distribution) is the outcome of a coin toss, where the outcome is either a head (success) or a tail (failure) and the probability of a head is a number between 0 and 1.

The PMF of a Bernoulli distribution is given by $P(X = x) = p^x(1-p)^{1-x}$, where x can be either 0 or 1. The CDF $F(x)$ of the distribution is 0 if $x < 0$, $1-p$ if

$0 \leq x < 1$, and 1 if $x \geq 1$. The mean and the variance of the distribution are p and $p(1-p)$, respectively.

If X_1, X_2, \dots, X_n are independent Bernoulli random variables, all with success probability p , then $\sum_{i=1}^n X_i$, which denotes the number of successes among the X_i 's, is a binomial random variable with number of trials = n and success probability p . The maximum likelihood estimate of p from a sample x_1, x_2, \dots, x_n from the Bernoulli random variable is the sample mean $\frac{1}{n} \sum_i x_i$, which is the proportion of successes in the sample.

To generate a random number X from the Bernoulli distribution, one has to first generate a random number R from the $U(0, 1)$ distribution (the uniform distribution between 0 and 1). If R is less than p , then X is set to 0; otherwise, X is set to 1.

Binomial Distribution

As mentioned above, a binomial distribution is the distribution of the sum of n independent Bernoulli random variables, all of which have the same success probability p . The quantity n is called the number of trials and p the success probability.

The PMF of a binomial distribution is given by

$$P(X = x) = \binom{n}{x} p^x (1-p)^{n-x}, \quad x = 0, 1, 2, \dots, n.$$

The mean and variance of the distribution are np and $np(1-p)$. For large values of n , the probability that the binomial random variable X takes the value x can be computed by approximating X by a normal variable Y with mean np and variance $np(1-p)$ and computing the probability that Y lies between $x - 0.5$ and $x + 0.5$.

The maximum likelihood estimate of p from a sample x_1, x_2, \dots, x_n from the binomial distribution is the ratio of the sample mean $\frac{1}{n} \sum_i x_i$ and n . To generate a random number from a binomial distribution, one can generate n Bernoulli random variables, all with probability p , and add them up. Alternatively, one can compute the CDF of the binomial distribution, generate $R \sim U(0, 1)$, and then take x as the random number from the binomial distribution if the CDF for $x - 1$ is less than R and the CDF for x is greater than or equal to R (this is often called the CDF-inversion method).

Several applications of the binomial distribution to educational data can be found in Novick and Jackson (1974). In one such application, the number of words

spelled correctly (out of a total of n words) by a student, where each word is equally difficult to spell, is assumed to follow the binomial distribution.

Geometric Distribution

If a sequence of independent Bernoulli random variables is generated with the same success probability p , $0 < p < 1$, the number of trials or failures before the first success follows a geometric distribution.

The PMF of a variable X following the geometric distribution is given by $P(X = x) = p(1 - p)^x$, $x = 0, 1, 2, \dots, \infty$. (Note that the number of possible values of a geometric random variable is countably infinite.)

The mean and variance of a geometric distribution are $\frac{1-p}{p}$ and $\frac{1-p}{p^2}$.

The geometric distribution is a special case of the negative binomial distribution. The sum of several independent geometric random variables with the same success probability is a negative binomial random variable.

The maximum likelihood estimate of p from a sample from the geometric distribution is $\frac{1}{1+\bar{x}}$, where \bar{x} is the sample mean.

The CDF of the geometric distribution for an integer r is given by $P(X \leq r) = 1 - (1-p)^{r+1}$. Using this expression, a random number from a geometric distribution can be generated by first generating $R \sim U(0, 1)$ and then computing the integer part of $\frac{\log(R)}{\log(1-p)}$.

For an example in educational testing where the geometric distribution can arise, see Lewis (2007).

Hypergeometric Distribution

Let an investigator draw a sample of n items without replacement from a population of N elements, of which M has a certain attribute. The number of elements in the sample with the attribute is a hypergeometric random variable. This distribution could arise when, for example, a group of examinees contains M examinees who passed a test and $N-M$ who failed; if one draws a sample of n examinees from the group, the number of examinees who passed in the sample is a hypergeometric random variable.

The PMF of the distribution is given by

$$P(X = x) = \frac{\binom{M}{x} \binom{N-M}{n-x}}{\binom{N}{n}}.$$

The mean and variance of the distribution are $\frac{nM}{N}$ and $\frac{(nM/N)(1-M/N)(N-n)}{N-1}$, respectively.

When $\frac{n}{N}$ is small and N is large, the hypergeometric distribution can be approximated by a binomial random variable with n trials and $p = \frac{M}{N}$.

The parameters of the distribution can be estimated from a sample of size n using the maximum likelihood

method. The estimate of N is the largest integer less than or equal to $\frac{nM}{x}$ and that of M is the largest integer less than or equal to $\frac{(N+1)x}{n}$.

To draw a random number from the distribution, one can construct a routine that simulates an experiment (by drawing elements at random) that will generate a hypergeometric random variable. Alternatively, one can compute the CDF of the distribution and then generate a hypergeometric random number with the help of a single $U(0, 1)$ random number and the CDF-inversion method.

Multinomial Distribution

The multinomial distribution is a multivariate generalization of the binomial distribution. Consider a trial that results in exactly one of some fixed finite number k of possible outcomes, with probabilities p_1, p_2, \dots, p_k (so that $p_i \geq 0$ for $i = 1, \dots, k$ and $\sum_{i=1}^k p_i = 1$), and there are n independent trials. Then let the random variables X_i indicate the number of times outcome number i was observed over the n trials. Then $X = (X_1, X_2, \dots, X_k)$ follows a multinomial distribution with parameters n and \mathbf{p} , where $\mathbf{p} = (p_1, p_2, \dots, p_k)$. An example where a multinomial random variable could occur is during the throw of a dice. Let X_i , $i = 1, 2, \dots, 6$, denote the number of times i is observed in n throws of a dice. Then $X = (X_1, X_2, \dots, X_6)$ has a multinomial distribution. If the dice is fair, then $p_i = \frac{1}{6}$ for all i .

The PMF of the multinomial distribution is given by

$$P(X_1 = x_1, X_2 = x_2, \dots, X_k = x_k) = \frac{n!}{x_1! x_2! \dots x_k!} p_1^{x_1} p_2^{x_2} \dots p_k^{x_k}$$

where $\sum_{i=1}^k x_i = n$. If $k = 2$, the multinomial distribution becomes a binomial distribution with n trials and success probability p_1 . When $X = (X_1, X_2, \dots, X_k)$ follows a multinomial distribution with the PMF given above, X_i follows a binomial distribution with n trials and success probability p_i . Hence, the mean and variance of X_i are np_i and $np_i(1 - p_i)$, respectively. The covariance between X_i and X_j is $-np_i p_j$.

The maximum likelihood estimate of p_i for a multinomial distribution is the ratio of the sample mean of x_i 's and n .

The straightforward way to generate a multinomial random variable is to simulate an experiment (by drawing n uniform random numbers that are assigned to specific bins according to the cumulative value of the \mathbf{p} vector) that will generate a multinomial random variable.

The multinomial distribution has found several applications in educational statistics. For example, this distribution is often applied to model the number of examinees who obtained a specific score (e.g., 70 out of 100) on an examination, or, the number of examinees who have a specific pattern of scores, for example, 0, 1, 1, 2, 1, 0, 0, \dots , in the items of an examination (see, e.g., Holland and Thayer (2000) and Holland (1990), for such applications).

Negative Binomial Distribution

As mentioned earlier, a negative binomial distribution is the distribution of the sum of independent geometric random variables. The number of failures before the n th success in a sequence of draws of Bernoulli random variables, where the success probability is p in each draw, is a negative binomial random variable. The PMF of the distribution is given by $P(X = x) = \binom{n+x-1}{n-1} p^n (1-p)^x$.

The mean and variance of a negative binomial distribution are $n \frac{1-p}{p}$ and $n \frac{1-p}{p^2}$.

The maximum likelihood estimate of p from a sample from the negative binomial distribution is $\frac{n}{n+\bar{x}}$, where \bar{x} is the sample mean.

If p is small, it is possible to generate a negative binomial random number by adding up n geometric random numbers. Another way is to generate a sequence of $U(0, 1)$ random variable values. When the number of those values less than p first reaches n , the number of values that are greater than p is a draw from the negative binomial distribution.

Poisson Distribution

The Poisson distribution describes the probability to find exactly x events in a given length of time if the events occur independently at a constant rate. In addition, the Poisson distribution can be obtained as an approximation of a binomial distribution when the number of trials n of the latter distribution is large, success probability p is small, and np is a finite number.

The PMF of the Poisson distribution is given by $P(X = x) = \frac{e^{-\lambda} \lambda^x}{x!}$, $x = 0, 1, \dots, \infty$, where λ is a positive number. Both the mean and variance of the Poisson distribution are equal to λ .

The maximum likelihood estimate of λ from a sample from the Poisson distribution is the sample mean.

If λ is large, the probability that a Poisson random variable X takes the value x can be obtained by approximating X by a normal variable Y with mean and variance λ and computing the probability that Y lies between $x - 0.5$ and $x + 0.5$.

It is possible to generate a Poisson random variable by generating a random number following the $U(0, 1)$ distribution and then using the CDF-inversion method.

The Poisson distribution has been applied in education, for example, by Novick and Jackson (1974).

Uniform (Discrete) Distribution

In fields such as survey sampling, the discrete uniform distribution often arises because of the assumption that each individual is equally likely to be chosen in the sample on a given draw. The PMF of a discrete uniform

distribution is given by $p(X = x) = \frac{1}{n+1}$, $x = 0, 1, \dots, n$, which implies that X can take any integer value between 0 and n with equal probability. The mean and variance of the distribution are $\frac{n}{2}$ and $\frac{n(n+2)}{12}$.

To generate a random number from the discrete uniform distribution, one can draw a random number R from the $U(0, 1)$ distribution, calculate $S = (n+1)R$, and take the integer part of S as the draw from the discrete uniform distribution.

Conclusions

Among the numerous discrete probability distributions, this article provides a brief overview of arguably the most popular eight such distribution, several of which have found applications in education (see, e.g., Evans *et al.* (2000), Johnson *et al.* (2005), and Johnson *et al.* (1997) for more details of these and many more discrete distributions). The choice of the specific distribution to be used in a specific application depends on several issues. If a specific distribution is used in practice to data of the type an investigator has (e.g., a multinomial distribution is often applied in practice to model the number of examinees who obtained a specific score on an examination), that distribution should be the first choice. If such knowledge is lacking, a sensible approach is to graphically plot the data and try to find a distribution that is expected to describe the data adequately. After fitting a distribution to a data set, methods of goodness-of-fit can be used to examine whether the distribution provides an adequate description of the data set.

Introduction

A frequently encountered problem in statistical applications to the educational sciences is that of determining to which of two or more groups an object of unknown group membership belongs. For example, we can think of there being two distinct groups of college students, those who graduate within 4 years and those who do not. A number of factors, such as high school grade point average, scores on college entrance exams, and participation in extracurricular activities, might have predictive power in this setting. What specific factor, or combination of factors, provides the most distinct separation between the two groups? Given the profile of a particular individual, what is our prediction as to his or her graduation status?

Broadly defined, discrimination and classification are multivariate statistical techniques for separating two or more populations, and deriving rules to predict group membership for new observations. The two terms are often used interchangeably, and indeed, the distinction between the two is a fuzzy one. Following Johnson and Wichern (2007) and other authors, we define these terms as follows:

1. *Discrimination*. A class of exploratory statistical methods to identify features or aspects of data that separate groups.
2. *Classification*. A body of statistical procedures that allocate observations into two or more well-defined groups.

It should be clear that the distinction between these two ideas is not sharp, as any method that effectively separates two or more populations will also provide a good rule for classifying future observations, and an optimal classification rule requires finding the clearest possible separation of the data.

Throughout this article we assume that our data consist of n observations, each known to have come from one of K populations, and an indicator of which population each observation is from. Thus, we have n observations of $(x_1, \dots, x_p, y)'$, where $(x_1, \dots, x_p)' \in \Omega \subseteq \mathbb{R}^p$ and $y \in \{1, \dots, K\}$, the population indicator. In the classification setting, these observations are sometimes called the training samples, as it is an often recommended practice to set aside a portion of the data to treat as the validation samples, on which the classifier's performance can be evaluated.

For an illustrative example, suppose $K = 2$ and $p = 2$ and consider the data in **Figure 1**. Thus, our data consist of bivariate observations from two populations, represented in **Figure 1** by triangles and circles. The goals of discriminant analysis and classification analysis for this example would be to find a boundary function and a classification boundary that best separates the circles and triangles. A number of methods for accomplishing these goals are described in the next section.

There are a number of other methods that have been suggested for classification; this article focuses on some of the most common approaches currently utilized for classification. Most textbooks in multivariate statistical methods (e.g., Johnson and Wichern, 2007; Rencher, 2002) provide an introduction to discriminant analysis and classification; multivariate texts usually focus on Fisher's methods and the k -nearest-neighbor approach. For a comprehensive discussion of classification and regression trees, see Breiman *et al.* (1984). A thorough review of most modern approaches to classification is available in Hastie *et al.* (2001).

Linear Methods

Regression Methods

One possible approach to discrimination and classification involves viewing the group indicator y as a (categorical) response variable, and running a regression of y on the predictor variables $\mathbf{x} = (x_1, \dots, x_p)'$.

Least-squares regression

For each $k = 1, \dots, K$ we define $y^{(k)}$ to take the value 1 if $y = k$ and 0 otherwise, so $y^{(k)}$ is an indicator of membership in group k . Note that $\Pr(y = k | \mathbf{x}) = \Pr(y^{(k)} = 1 | \mathbf{x}) = E(y^{(k)} | \mathbf{x})$. We next conduct K linear regressions, of $y^{(k)}$ on \mathbf{x} for each $k = 1, \dots, K$. That is, we fit the models

$$E(y^{(k)} | \mathbf{x}) = \beta_0^{(k)} + \beta_1^{(k)} x_1 + \dots + \beta_p^{(k)} x_p$$

estimating $(\beta_0^{(k)}, \beta_1^{(k)}, \dots, \beta_p^{(k)})'$ by the least-squares method. Denote the least-squares estimate of $\beta_i^{(k)}$ by $\hat{\beta}_i^{(k)}$ for $i = 0, 1, \dots, p$. We can then estimate the conditional group membership probabilities by the fitted values

$$\hat{\Pr}(y = k | \mathbf{x}) = \hat{\beta}_0^{(k)} + \hat{\beta}_1^{(k)} x_1 + \dots + \hat{\beta}_p^{(k)} x_p$$

for $k = 1, \dots, K$. It can be shown that the least-squares estimates satisfy $\sum_{k=1}^K \hat{\beta}_0^{(k)} = 1$ and $\sum_{k=1}^K \hat{\beta}_i^{(k)} = 0$ for

$i = 1, \dots, p$. An immediate consequence of this result is that $\sum_{k=1}^K \hat{\Pr}(y = k|x) = 1$ for any value of \mathbf{x} . On the other hand, it is possible for a fitted probability to be less than 0 or greater than 1. If we are in the classification setting, we would classify a new observation \mathbf{x}_0 as belonging to the group k for which $\hat{\Pr}(y = k|\mathbf{x}_0)$ is maximized.

The least-squares regression approach to discrimination and classification is simple, intuitive, and easy to implement. Unfortunately, in addition to the unattractive property of negative estimated probabilities, this approach is well known to be prone to masking, in which one or more categories is missed entirely by the classification rule (see Hastie *et al.*, 2001, for an example).

Logistic regression

An alternative to least-squares regression that guarantees the fitted probabilities will be between 0 and 1 is the method of multinomial logistic regression. We arbitrarily designate the last group, group K , to serve as the baseline category. In the multinomial logit model,

$$\log \frac{\Pr(y = k|x)}{\Pr(y = K|x)} = \beta_0^{(k)} + \beta_1^{(k)} x_1 + \dots + \beta_p^{(k)} x_p$$

for $k = 1, \dots, K-1$. According to this model, the ratio of any two group membership probabilities is a log-linear function of \mathbf{x} , since we have

$$\log \frac{\Pr(y = j|x)}{\Pr(y = k|x)} = (\beta_0^{(j)} - \beta_0^{(k)}) + (\beta_1^{(j)} - \beta_1^{(k)}) x_1 + \dots + (\beta_p^{(j)} - \beta_p^{(k)}) x_p$$

for any j and k , including the baseline category K if we take $\beta_i^{(K)} = 0$ for $i = 0, 1, \dots, p$, a convenient choice to ensure

model identifiability. The group membership probabilities can be solved for explicitly, and are given by

$$\Pr(y = k|x) = \frac{\exp(\beta_0^{(k)} + \beta_1^{(k)} x_1 + \dots + \beta_p^{(k)} x_p)}{\sum_{j=1}^K \exp(\beta_0^{(j)} + \beta_1^{(j)} x_1 + \dots + \beta_p^{(j)} x_p)}$$

The unknown parameters are estimated by the method of maximum likelihood (Agresti, 2002); maximum likelihood estimates are easily found using any statistical software package (though care must be taken to make sure the model parametrization is what the user understands it to be). In the classification problem, a new observation \mathbf{x}_0 is classified as belonging to the group k for which $\hat{\Pr}(y = k|\mathbf{x}_0)$ is maximized.

Example

Consider the illustrative example introduced above. Figure 2 contains the same scatterplot introduced above with two linear boundaries; the dashed line corresponds to the boundary based on least squares and the solid line corresponds to logistic regression. Any point above (and right) of the line would be classified as a triangle; below (and left) would be classified as a circle.

Fisher Discrimination

The goal of discrimination analysis is to transform the data in such a way that observations drawn from different populations will be well separated on the transformed scale. Fisher discrimination finds the one or more linear combinations of \mathbf{x} that best separate the groups. We first address the problem of discriminating between two groups, and then generalize to the K -population case.

Figure 1 A simple two-group discrimination/classification example with two predictor variables.

Figure 2 The least-squares (dashed line) and logistic regression (solid line) classification boundaries for the example data set.

Fisher discrimination for two populations

Consider the linear transformation $u = \mathbf{a}'\mathbf{x}$ for $\mathbf{a} \in \mathbb{R}^p$. What choice of \mathbf{a} provides the clearest separation between the two groups? One possible answer is the choice that maximizes the absolute value of the t -statistic for comparing population means. Let \bar{u}_1 and \bar{u}_2 denote the means of the transformed values from populations 1 and 2, respectively, and let s_u denote the pooled sample standard deviation. We wish to make

$$t = \frac{\bar{u}_1 - \bar{u}_2}{s_u \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}}$$

as large in magnitude as possible. Let $\bar{\mathbf{x}}_1$ and $\bar{\mathbf{x}}_2$ denote the sample mean vectors and \mathbf{S} the pooled sample covariance matrix, so $\bar{u}_k = \mathbf{a}'\bar{\mathbf{x}}_k$ for $k = 1, 2$ and $s_u^2 = \mathbf{a}'\mathbf{S}\mathbf{a}$. We seek the value of \mathbf{a} that maximizes

$$\frac{(\bar{u}_1 - \bar{u}_2)^2}{s_u^2} = \frac{(\mathbf{a}'(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2))^2}{\mathbf{a}'\mathbf{S}\mathbf{a}}$$

which turns out to be $\mathbf{a} = \mathbf{S}^{-1}(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2)$. The linear combination $(\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2)'\mathbf{S}^{-1}\mathbf{x}$ is called Fisher's linear discriminant function. Note that there is no assumption of multivariate normality here. On the other hand, for the notion of maximizing a distance measured in standard deviations to make sense, we must implicitly assume a constant covariance matrix across groups.

Fisher discrimination for K populations

Let x_{kl} denote the l th observation from group k for $k = 1, \dots, K$ and $l = 1, \dots, n_k$. As above, we let $\bar{\mathbf{x}}_k$ denote the k th sample mean, and let $\bar{\mathbf{x}}$ denote the overall mean. We compute the matrices

$$\mathbf{B} = \sum_{k=1}^K n_k (\bar{\mathbf{x}}_k - \bar{\mathbf{x}})(\bar{\mathbf{x}}_k - \bar{\mathbf{x}})'$$

and

$$\mathbf{W} = \sum_{k=1}^K \sum_{l=1}^{n_k} (x_{kl} - \bar{\mathbf{x}}_k)(x_{kl} - \bar{\mathbf{x}}_k)'$$

These are the between groups and within groups sums of squares matrices for a MANOVA of \mathbf{x} by group. If \mathbf{B} is a measure of the variability among the $\bar{\mathbf{x}}_k$'s, then $\mathbf{a}'\mathbf{B}\mathbf{a}$ is a measure of the variability among the $\mathbf{a}'\bar{\mathbf{x}}_k$'s. Similarly, as \mathbf{W} is a measure of the variability among the \mathbf{x} -values within a group, $\mathbf{a}'\mathbf{W}\mathbf{a}$ measures the variability of the $\mathbf{a}'\mathbf{x}$'s. The first linear discriminant is given by the vector \mathbf{a}_1 that maximizes the ratio

$$\frac{\mathbf{a}'\mathbf{B}\mathbf{a}}{\mathbf{a}'\mathbf{W}\mathbf{a}}$$

This turns out to be the eigenvector associated with the largest eigenvalue of $\mathbf{W}^{-1}\mathbf{B}$. The second linear discriminant \mathbf{a}_2 maximizes the above ratio subject to $\mathbf{a}_1'\mathbf{W}\mathbf{a}_2 = 0$.

This turns out to be the eigenvector for the second largest eigenvalue of $\mathbf{W}^{-1}\mathbf{B}$, and so on. There are as many linear discriminants as the rank of the matrix \mathbf{B} .

While Fisher's objective for the linear discriminants was to maximally separate values from different populations, Fisher discrimination can be used as the basis for a classification rule also. Let \mathbf{A} be a matrix whose rows are the first few linear discriminants. Given the value x_0 , classify this case to the population k for which the distance between $\mathbf{A}\mathbf{x}_0$ and $\mathbf{A}\bar{\mathbf{x}}_k$ is smallest.

Fisher's linear discriminant analysis is equivalent (up to a constant of proportionality) to the least-squares regression of the indicator variable on \mathbf{x} .

Support Vector Classifiers

Support vector machines are a relatively modern approach to classification as compared to the other methods described above.

Consider the problem of classifying observations into one of two groups. We say that the observed data are perfectly linearly separable when there exists a linear function $u(\mathbf{x}) = a_0 + \mathbf{a}'\mathbf{x}$ that perfectly separates the two groups in Ω . That is, there exists a vector \mathbf{a} such that $u(\mathbf{x}) > 0$ for all individuals in one group and $u(\mathbf{x}) < 0$ for all observations in the second group. The plane defined by $u(\mathbf{x})$ is called the separating hyperplane.

When the two groups are perfectly separable, there will be infinitely many separating hyperplanes. In order to define a unique solution to the separating hyperplane problem, the method searches for the hyperplane that perfectly separates the two groups and maximizes the distance from the plane to the nearest observed data point; this hyperplane is called the maximum margin hyperplane. Classification is then achieved by the following rule:

$$\text{Classify into } \begin{cases} \text{Group 1} & \text{if } u(x_0) \geq C \\ \text{Group 2} & \text{if } u(x_0) \leq -C \end{cases} \quad [1]$$

The region defined by $|u(\mathbf{x})| < C$ defines the margin, where we are unable to classify observations into either group. Any observed data point on the boundary of the margin is called a support vector.

In most applied problems, the two groups will not be perfectly linearly separable. In such cases, the support vector classifier allows for some observations to be incorrectly classified. The method defines a set of slack variables that allow some of the observations within a group to violate the classification rule in [1]; the size of the slack variable is the distance between the data point and the boundary of group margin. The support vector classifier then maximizes the width of the margin while bounding the size of the slack variables below some predefined constant.

Basis Expansion Methods

In many applications, a linear boundary between the groups will not be adequate for accurate classification. In such cases we can often still rely on linear classifiers, but in a higher dimensional space. In our treatment of the classification problem, we have a p -dimensional vector \mathbf{x} to perform classification. The idea of basis expansion methods is to map this p -dimensional vector into a higher dimensional space, where linear classification performs well.

Consider the example represented in **Figure 3** where the circles and triangles are perfectly separated by the circle defined by $(x_1 - 1)^2 + (x_2 - 1)^2 = 1$. Expanding the squares, we find that classification can be achieved by classifying \mathbf{x}_0 into the circle group if

$$x_1^2 - 2x_1 + 1 + x_2^2 - 2x_2 + 1 < 1$$

and into the triangle group if the inequality is reversed. Therefore, we can get perfect linear separability if we expand from the two-dimensional space (x_1, x_2) to the four-dimensional space (x_1, x_2, x_1^2, x_2^2) . The projection of the linear classifier in the expanded space onto the two-dimensional space creates a nonlinear classifier. Popular expansion methods include polynomial expansion, spline expansion, and kernelization methods.

Basis expansion can also help with the example presented in the introduction (see **Figure 1**). If we expand the logistic regression model to include quadratic and cubic terms, the resulting classification rule fits the data much better as seen in **Figure 4**.

Density-Based Classification Methods

Let f_k denote the probability density function for population k , that is, $x|y = k \sim f_k(\cdot)$, for $k = 1, \dots, K$. The basic

Figure 3 An example where groups are perfectly separated by the circle $x_1^2 + x_2^2 = 1$.

idea in density-based classification is to classify a new observation \mathbf{x}_0 as coming from the population k where the ratio $f_k(\mathbf{x}_0)/f_i(\mathbf{x}_0)$ is high for $i \neq k$. Two more considerations that enter are population prevalence and cost of misclassification. We first illustrate with $K = 2$ populations and then extend to the more general case.

The prevalence of a population is the marginal probability that an object belongs to the population, given no information on the value of \mathbf{x} . Let populations 1 and 2 have prevalence p_1 and p_2 , respectively, so that $p_1 + p_2 = 1$. Misclassification cost accounts for the fact that some mistakes are more severe than others. Let $c(1|2)$ denote the cost of classifying a population 2 object as coming from population 1, and let $c(2|1)$ be the cost of classifying a population 1 object as population 2. We show here that the classification rule to minimize the overall expected cost of misclassification is to classify a new observation \mathbf{x}_0 as coming from population 1 if

$$\frac{f_1(\mathbf{x}_0)}{f_2(\mathbf{x}_0)} > \frac{p_2 c(1|2)}{p_1 c(2|1)} \quad [2]$$

and to classify as population 2 otherwise.

To see why the above rule is optimal, let $EC_1(\mathbf{x})$ denote the expected cost of classifying \mathbf{x} as population 1, and $EC_2(\mathbf{x})$ the expected cost of classifying as population 2. The optimal classification rule will choose population 1 if $EC_1(\mathbf{x}) < EC_2(\mathbf{x})$ and population 2 otherwise.

Now

$$EC_1(\mathbf{x}) = c(1|2)\Pr(y = 2|\mathbf{x}) = c(1|2) \frac{p_2 f_2(\mathbf{x})}{p_1 f_1(\mathbf{x}) + p_2 f_2(\mathbf{x})}$$

and

$$EC_2(\mathbf{x}) = c(2|1)\Pr(y = 1|\mathbf{x}) = c(2|1) \frac{p_1 f_1(\mathbf{x})}{p_1 f_1(\mathbf{x}) + p_2 f_2(\mathbf{x})}$$

Figure 4 The classification rule based on a logistic regression model that includes both quadratic and cubic terms for the two predictor variables x_1 and x_2 .

so we will classify as population 1 if

$$c(1|2)p_2f_2(\mathbf{x}) < c(2|1)p_1f_1(\mathbf{x})$$

and population 2 otherwise. Thus, [2] describes the classification rule that minimizes the expected cost of misclassification.

We now consider the general K -population case. Again we denote the prevalence of population k by p_k ; this is the marginal probability $p_k = \Pr(y = k)$ for $k = 1, \dots, K$. Let the misclassification cost $c(i|j)$ denote the cost of classifying an object from population j into population i . Assume that $c(i|i) = 0$ for each i . Finally, we again let $EC_k(\mathbf{x})$ denote the expected cost of classifying the value \mathbf{x} as population k . Then

$$EC_k(\mathbf{x}) = \sum_{j \neq k} c(k|j) \Pr(y = j|\mathbf{x}) = \frac{\sum_{j \neq k} c(k|j) p_j f_j(\mathbf{x})}{\sum_{j=1}^K p_j f_j(\mathbf{x})}$$

Given the observed value \mathbf{x}_0 , we should classify to the population k to minimize $EC_k(\mathbf{x}_0)$, that is, to the population k for which

$$\sum_{j \neq k} p_j c(k|j) f_j(\mathbf{x}_0) \text{ is minimized}$$

If all misclassification errors are equally costly, that is, if the $c(i|j)$ are equal for all $i \neq j$, this rule simplifies to choosing the population k to maximize $p_k f_k(\mathbf{x}_0)$.

Normal Populations with Equal Variance

Suppose all K populations are multivariate normal distributions with a common covariance matrix, that is, $\mathbf{x}|y = k \sim N_p(\mu_k, \Sigma)$ for $k = 1, \dots, K$. First suppose $K = 2$. Then

$$\frac{f_1(\mathbf{x})}{f_2(\mathbf{x})} = \exp \left\{ -\frac{1}{2}(\mu_1 + \mu_2)' \Sigma^{-1}(\mu_1 - \mu_2) + (\mu_1 - \mu_2)' \Sigma^{-1} \mathbf{x} \right\}$$

and the classification rule [2] reduces to assigning \mathbf{x}_0 to population 1 if

$$-\frac{1}{2}(\mu_1 + \mu_2)' \Sigma^{-1}(\mu_1 - \mu_2) + (\mu_1 - \mu_2)' \Sigma^{-1} \mathbf{x}_0 > \log \left[\frac{p_2 c(1|2)}{p_1 c(2|1)} \right]$$

and population 2 otherwise.

For $K \geq 3$ there is not much simplification for the case of general misclassification costs. If all misclassification costs are equal, we assign \mathbf{x}_0 to the population k , which maximizes

$$\log p_k - \frac{1}{2}(\mathbf{x}_0 - \mu_k)' \Sigma^{-1}(\mathbf{x}_0 - \mu_k) \quad [3]$$

If the K populations are of equal prevalence, this rule reduces to classifying to the population whose mean is closest to \mathbf{x}_0 in Mahalanobis distance. Also, since the quadratic term in [3] is the same for all k , an equivalent classification rule is to choose k to maximize

$$\log p_k - \frac{1}{2} \mu_k' \Sigma^{-1} \mu_k + \mu_k' \Sigma^{-1} \mathbf{x}_0$$

called the linear discriminant score of \mathbf{x}_0 for the k th population.

Normal Populations with Unequal Variances

Now suppose that $\mathbf{x}|y = k \sim N_p(\mu_k, \Sigma_k)$ for $k = 1, \dots, K$. Again, we first consider $K = 2$. Here

$$\begin{aligned} \log \left(\frac{f_1(\mathbf{x})}{f_2(\mathbf{x})} \right) &= -\frac{1}{2} \mathbf{x}' (\Sigma_1^{-1} - \Sigma_2^{-1}) \mathbf{x} + (\mu_1' \Sigma_1^{-1} - \mu_2' \Sigma_2^{-1}) \mathbf{x} \\ &\quad - \frac{1}{2} \log \left(\frac{|\Sigma_1|}{|\Sigma_2|} \right) - \frac{1}{2} (\mu_1' \Sigma_1^{-1} \mu_1 - \mu_2' \Sigma_2^{-1} \mu_2) \end{aligned}$$

and thus linear discriminant in the classification rule for the case of equal covariance matrices becomes a quadratic discriminant in the general case.

For $K \geq 3$, assuming equal misclassification costs, we would assign \mathbf{x}_0 to population k that maximizes

$$\log p_k - \frac{1}{2} \log |\Sigma_k| - \frac{1}{2} (\mathbf{x}_0 - \mu_k)' \Sigma_k^{-1} (\mathbf{x}_0 - \mu_k)$$

the quadratic discriminant score of \mathbf{x}_0 for population k .

Density-Based Classification in Practice

In practical applications, even where the assumption of multivariate normality is reasonable, parameter values will almost never be known. The usual practice is simply to replace them with their estimators, thus using the above formulas with the sample means $\bar{\mathbf{x}}_k$ in place of the μ_k , sample covariance matrices \mathbf{S}_k for the Σ_k , and the pooled sample covariance matrix $\mathbf{S}_{\text{pooled}}$ for Σ . Even in cases where the normality assumption is violated, it is often possible to transform the data to a scale on which the data are approximately normal. Finally, in problems of moderate dimension, and with very large data sets, it may be feasible to do density-based classification using non-parametric estimates of the unknown density functions using kernel or spline methods.

Classification Trees

The classification-tree approach to a classification problem is based on the notion of decision trees, an example of which is given here. Suppose you have to get to a meeting across town, to which you can walk, take a bus or subway, or hire a taxi cab. You would rather not go by taxi cab, but a bus or subway will take at least 10 min. If your meeting starts in less time than that, you have no choice but to take a taxi. Your preference would be to walk, but only if the weather is nice, and that takes 30 min. You generally prefer the subway to a bus, but the subway is uncomfortable if it is too hot. **Figure 5** gives a decision tree to help you choose your mode of transportation. The endpoints of the decision tree form a partition of the space Ω . This is

Figure 5 Decision tree for mode of transportation: Take a taxi if time to meeting is less than 10 min, otherwise take a bus if it's too hot ($\text{temp} > 80$), and a subway if it's too cold ($\text{temp} < 40$); walk if the temperature is moderate (40–80) and you have time ($\text{time} > 30$).

Figure 6 In this plot green indicates a taxi, gray indicates the bus, red indicates the subway, and blue indicates walking.

illustrated in **Figure 6** where we plot time until the meeting on the x -axis and temperature on the y -axis, and use four colors to indicate appropriate mode of transportation given the conditions.

A classification tree is a decision tree for the decision to which population to classify an object \mathbf{x} . There are a number of algorithms for constructing classification trees, the best known of which is the CART algorithm of Breiman *et al.* (1984). The following discussion is sufficiently general as to apply to most algorithms used in practice.

A classification tree is built from top to bottom. The top node contains the entire space Ω and thus the entire training data set. At this and every subsequent node, the algorithm must determine whether the tree should be further split, and if so, how. We address the second point first. Consider an algorithm that constructs splits based on a single variable (it is also possible to split based on linear combinations of the variables). Assuming all our predictors are quantitative, we must consider all splits of the form $\{x_i < s\}$ versus $\{x_i \geq s\}$. At the first node (the top of the tree), there are at most $p(n-1)$ such allowable splits. The algorithm selects the split that maximizes the reduction in node impurity, a measure of the heterogeneity among the training cases classified to that node. Two common measures are the Gini index

$$1 - \sum_{k=1}^K \left(\frac{m_k}{m} \right)^2$$

and the deviance

$$-2 \sum_{k=1}^K m_k \log \left(\frac{m_k}{m} \right)$$

where m is the number of training cases classified to the node being considered for splitting, and m_k is the number of those that are of population k . Unless node impurity is zero, that is, unless $m_k = m$ for some k , a split can be found for which the combined impurity of the two new nodes will be less than that of the parent node. However, this does not necessarily mean that extending the tree is a good idea. Most algorithms use a stopping rule that considers both the number of training cases remaining at the node under consideration and the degree of heterogeneity among those cases, stopping if either of these quantities is too small. One possible strategy is to set highly stringent stopping criteria, to intentionally overgrow the tree and then prune it back at the end. We discuss the method of cost-complexity pruning below.

Let T_0 be a tree grown with a sufficiently stringent stopping rule that the tree is guaranteed to provide a good fit to the training data. For every $\alpha \geq 0$ we define T_α as the subtree of T_0 (i.e., every split in T_α is also in T_0) that minimizes the cost-complexity criterion

$$C_\alpha(T) = Q(T) + \alpha|T|$$

where $Q(T)$ is some measure of the misclassification error for the tree T and $|T|$ is the number of terminal nodes. The former quantity represents the cost of misclassification and the latter penalizes for tree complexity. The family of trees $\{T_\alpha\}$ is found by weakest link pruning, wherein the terminal node that produces the smallest reduction in misclassification error is pruned away; this process is repeated all the way back up to the single node tree T_∞ in which every case is classified to the population with the greatest prevalence in the training sample. From

Figure 7 Decision tree for the circles and triangles example.

Figure 8 The classification tree rule for the circles and triangles example.

the family of trees $\{T_\alpha\}$, the appropriate value of α , and hence the final classification tree, is found by cross-validation.

Among the strengths of this approach to classification are: (1) the absence of any assumptions about the distributions of $x|y$; (2) the ease with which categorical and ordinal predictors are incorporated into the algorithm (a categorical predictor with q levels requires that $2^{q-1} - 1$ splits be considered, and ordinal variables are treated no differently than continuous, with $q - 1$ splits to consider); and (3) the ability of tree-based methods to make the most

of incomplete observations (a partial observation is dropped only if it is missing the variable being split on).

The classification tree for the circles and triangles example introduced earlier is depicted in **Figures 7 and 8**. The resulting classification rule is very similar to the one derived by cubic logistic regression.

k-Nearest-Neighbor Classification

The k -nearest-neighbor approach to classification is a relatively simple approach to classification that is completely nonparametric. Given a point \mathbf{x}_0 that we wish to classify into one of the K groups, we find the k observed data points that are nearest to \mathbf{x}_0 . The classification rule is to assign \mathbf{x}_0 to the population that has the most observed data points out of the k -nearest neighbors. Points for which there is no majority are either classified to one of the majority populations at random, or left unclassified.

The advantage of nearest-neighbor classification is its simplicity. There are only two choices a user must make: (1) the number of neighbors, k and (2) the distance metric to be used. Common choices of distance metrics include Euclidean distance, Mahalanobis distance, and city-block distance. The number of neighbors is usually selected by either cross-validation or testing the quality of the classifier on a second, test data set.

Glossary

Bayesian inference – A kind of statistical inference that makes extensive use of the Bayes theorem to update probability that a hypothesis may be true as evidence accumulates.

Item response theory – A mathematical theory that uses statistical models to describe the interactions between an individual and items from a questionnaire under a stimulus-response framework.

Maximum likelihood method – A statistical method that fits a model to data. The method is based upon the likelihood of observing the collection of data points under the specified model.

Introduction

The empirical Bayes (EB) approach can be viewed from at least two perspectives: first, as a technical tool for borrowing information across individual cases for performing statistical inference; and, second, as a compromise between two statistical paradigms – Bayesian and frequentist. While the second topic is important for understanding EB's role within the inferential paradigms, it is too vast to do full justice to in this article.

In education, the EB approach is particularly useful for enhancing the quality of educational measurements (student proficiency, teacher performance, school achievement, etc.) when multiple statistical units (schools, teachers, students, etc.) are measured.

Let us illustrate how the EB procedure allows information to be borrowed across individual units for improving the quality of educational measurement. Suppose that a state is interested in using a new portfolio-assessment method for evaluating student performance on language ability. The goal is to evaluate the feasibility of replacing the traditional test with the new method. One is also interested in obtaining an accurate estimate of each school's performance so that they can design enhancement programs and allocate resources. The state administers the new assessment method to a sample of 100 students from each of ten randomly selected schools. The minimum and maximum portfolio scores are 0 and 800, respectively. Table 1 displays the corresponding mean scores.

The question is: Are the mean scores good estimates for reporting school performance?

Because of intra-school variability, a school's score depends upon the sample drawn: if a school's student population is heterogeneous, then the sample-to-sample variation may be large. Due to haphazard chance, a school may therefore appear not to be performing up to its true potential; the converse could also be true.

The primary idea behind EB is to use both local (sample mean score) and global (embedded in the distribution of the mean scores across schools) information to enhance the quality of the estimates. One can think of the ten scores in Table 1 as a sample from the universe of the state's schools. The performance distribution of the state's schools can be used to inform the estimates for individual schools. It can be mathematically proven that – when both local and global data are used – the precision of the estimates for individual schools is better than when only local information is used, in terms of root mean square error.

EB Normal–Normal Model

The EB setup is easily illustrated when both the global and local models are normally distributed: the global model states that the true mean scores θ_i are sampled independently from a common underlying distribution, and are not directly observed; and that they follow a normal distribution with mean μ and variance σ_θ^2 :

$$\theta_i \sim N(\mu, \sigma_\theta^2). \quad [1]$$

The above distribution is the so-called prior distribution. The local model allows for noise in measuring the score of the individual member and that the observed values of individual score y_i represent a realization of another normal distribution centered at θ_i :

$$y_i | \theta_i \sim N(\theta_i, \sigma_y^2). \quad [2]$$

This hierarchy is depicted in Figure 1. The normal prior distribution defined in [1] provides a model for global information, whereas the distribution $f_{\theta_i}(y)$ (the normal distribution in [2]) contains local information about the individual unit. This structure is rather general and can be applied to a variety of situations. For example, in the school-performance example, the observed values are collected at the student level. Suppose that each school

Figure 1 Data generating mechanism in EB approach.

contains a sample of \mathcal{J} students; that the score of the j th student from the i th school is denoted by x_{ij} , $i = 1, \dots, I$, $j = 1, \dots, \mathcal{J}$; and that the student scores follow a distribution with mean θ_i and variance σ_x^2 . Then, the mean score of each school is given by $y_i = (1/\mathcal{J}) \sum_{j=1}^{\mathcal{J}} x_{ij}$, and so:

$$y_i | \theta_i \sim N\left(\theta_i, \frac{\sigma_x^2}{\mathcal{J}}\right) \quad [3]$$

The structure in **Figure 1** is, of course, not confined to normality. Some other examples are presented later in this article.

The EB approach involves the following steps:

(S1) Estimate the global structure, using the marginal distribution of the observed data.

(S2) Estimate the value for each individual unit using global information from step S1, together with local information collected from each individual unit. This specific step of inference is through the posterior distribution of individual true (unobserved) measurement of each unit given the data.

To elaborate on (S1) and (S2), use notation of [1] and [2]. First, consider the case in which σ_θ^2 and σ_y^2 are both known, with only μ unknown and estimated in (S1). Because y_i are independently normally distributed with mean μ and variance $\sigma_\theta^2 + \sigma_y^2$, the maximum-likelihood estimate (MLE) for μ is the sample mean:

$$\hat{\mu} = \bar{y} = \frac{1}{I} \sum_{i=1}^I y_i \quad [4]$$

(S2) involves estimating the true but unobserved mean score for each school. The typical EB estimate for a two-level model of this kind would be the posterior mean of the unknown true mean score given the observed data and the estimated global structure:

$$\hat{\theta}_i^{EB} = E(\theta_i | y_i, \mu) \quad [5]$$

From normal theory, the conditional distributions of θ_i given y_i are independently normally distributed:

$$\theta_i | y_i \sim N(B\mu + (1-B)y_i, (1-\beta)\sigma_y^2) \quad [6]$$

where $B = \frac{\sigma_y^2}{\sigma_y^2 + \sigma_\theta^2}$. Therefore, the EB estimate $\hat{\theta}_i^{EB}$ is given by

$$\hat{\theta}_i^{EB} = B\bar{y} + (1-B)y_i \quad [7]$$

from plugging in the estimated parameter for the global structure – that is, replacing μ with $\hat{\mu} = \bar{y}$. The uncertainty associated with the EB estimate $\hat{\theta}_i^{EB}$ is based on the variance $V(\theta_i | y_i, \mu)$ of the posterior distribution, with 95% confidence interval:

$$(\hat{\theta}_i^{EB} - 1.96 \times \sqrt{(1-B)\sigma_y^2}, \hat{\theta}_i^{EB} + 1.96 \times \sqrt{(1-B)\sigma_y^2}) \quad [8]$$

Note that the EB approach – in contrast with general Bayesian approaches – always directly estimates the global structure from empirical data and then uses plug-in estimates of the global structure for estimating individual locality. The E in EB refers to this plug-in principle. To further illustrate the plug-in principle, retain the normal-normal case with the parameter σ_θ^2 also unknown. The marginal MLE for the pair (μ, σ_θ^2) is given by

$$\hat{\mu} = \bar{y} = \frac{1}{I} \sum_{i=1}^I y_i \quad [9a]$$

$$\hat{\sigma}_\theta^2 = \max(s^2 - \sigma_y^2, 0) \quad [9b]$$

where $s^2 = (1/I) \sum_{i=1}^I (y_i - \bar{y})^2$ is the sample variance of the observed y_i . Following the plug-in principle, the EB estimate $\hat{\theta}_i^{EB}$ for an individual school is now

$$\hat{\theta}_i^{EB} = \hat{B}\bar{y} + (1-\hat{B})y_i \quad [10]$$

where $\hat{B} = \sigma_y^2 / (\sigma_y^2 + \hat{\sigma}_\theta^2)$, in which $\hat{\sigma}_\theta^2$ is plugged in from [9b]. The confidence intervals take form [8], although now using \hat{B} rather than B . In general, the EB-based confidence interval would be too narrow because it does not account for the uncertainty associated with the estimation of \hat{B} . There are different correction methods, including jack-knife and bootstrap. The reading list includes articles that

cover methods not requiring a fully Bayesian specification. An alternative approach is described in the section on EB application to the National Assessment of Educational Progress (NAEP).

Example

The values in **Table 1** were simulated from a two-level process with $\mu = 500$, $\sigma_\theta = 20$, $\sigma_x = 100$, $I = 10$, and $J = 100$. If we assume σ_x to be known, then the variance of the mean score $\sigma_j^2 = 100^2/100 = 100$. Thus, the estimates for (μ, σ_θ^2) are given by (9) and applied to **Table 1**, which results in $\hat{\mu} = 495.8$, $\hat{\sigma}_\theta = 15.3$, and $\hat{B} = 0.3$. **Figure 2** compares the EB estimates and the values of the mean scores, which are MLEs based only on data from one specific school.

The EB estimate in [10] is a weighted linear combination of two sources of information: globally from \bar{y} and locally from y_i . Effectively, the EB approach amounts to a shrinkage effect that pulls all the MLEs toward the overall mean. The strength of the shrinkage depends on the relative heterogeneity of data at the global and local levels. If the true mean scores are relatively homogeneous (small σ_θ^2 or large σ_j^2), then the factor B should be close to 1 – implying that the shrinkage effect would be large, and vice versa. The shrinkage factor B in this case is analogous to the intraclass correlation in classical test theory – the ratio of the between-student variation to the sum of the between-student variation and the between-school variation.

The EB estimate satisfies many desirable properties within the decision-theoretic framework. The square loss function is often used to quantify the risk for choosing one decision (estimator) over another. If the true value of the target parameter is θ – estimated by $\hat{\theta}$ – then the squared loss function is $L(\theta, \hat{\theta}) = (\theta - \hat{\theta})^2$. In the normal-normal setting, if our interest is in the value of θ_i for each individual unit, it can be proven that – under squared loss – the EB estimator is superior to any other estimator, including those that are based on the observed data y_i alone. When the prior distribution for θ is known, then the EB estimator is ideal for any symmetric loss function. When the global

structure is not known or the setup is more general, various versions of EB estimators have been proposed. Many authors have searched for optimality under various scenarios (Stein, Robbins, Maritz, Morris, Efron, Louis, etc.).

The structure in **Figure 1** can be further generalized in several directions. Examples with different parametric choices for local and global levels are presented below.

EB gamma-Poisson Model

Consider data collected over spelling errors made by school children. In a dictation test, school children are given a fixed number of J words. The number of errors that the i th child made can be modeled as a Poisson process with rate parameter θ_i – assumed to vary across individual children (Van Duijn and Bockenholt, 1995). It is mathematically convenient to assume that the θ_i follows a gamma distribution, that is, the global structure for spelling error rate parameters can be specified through the following two-parameter prior distribution:

$$p_{\text{Gamma}}(\theta_i | \alpha, \beta) = \frac{\theta_i^{\alpha-1} \beta^\alpha e^{-\beta\theta_i}}{\Gamma(\alpha)}, \quad \theta_i, \alpha, \beta > 0 \quad [11]$$

in which α and β are, respectively, the shape and rate (inverse scale) parameters, and Γ is the gamma function. If α is a positive integer, then $\Gamma(\alpha) = (\alpha-1)! = (\alpha-1)(\alpha-2) \dots 3 \times 2 \times 1$. Conditional on θ_i , the total number of spelling errors for child i is given by the Poisson count model:

$$P(Y_i = y_i | \theta_i) = \frac{e^{-\theta_i} \theta_i^{y_i}}{y_i!} \quad [12]$$

where $y_i = 0, 1, 2, \dots$. The marginal distribution for Y_i then is a negative binomial distribution:

$$P(Y_i = y_i) = \left(\frac{\beta}{\beta + 1} \right)^\alpha \frac{\Gamma(\alpha + y_i)}{\Gamma(\alpha)} \frac{1}{y_i!} \frac{1}{(\beta + 1)^{y_i}} \quad [13]$$

The standard method for estimating (α, β) is maximum likelihood, with the likelihood function assembled from contributions [13]. It is convenient to reparameterize by the mean of the gamma distribution $\mu = \alpha/\beta$. The

Figure 2 Shrinkage effect from the EB approach in school-performance example.

MLE of μ is $\bar{y} = (1/I) \sum_{i=1}^I y_i$, but there is no closed-form solution for α . One can also use the method of moments for the global structure, that is, matching the moments of the marginal distributions with empirical moments and then solving for the required parameters. This produces (Maritz, 1969):

$$\hat{\mu} = \bar{y} \quad [14a]$$

$$\hat{\beta} = \frac{\bar{y}^2}{(s^2 - \bar{y})}, \text{ if } s^2 > \bar{y} \quad [14b]$$

where $s^2 = \frac{1}{I} \sum_{i=1}^I (y_i - \bar{y})^2$. If $s^2 < \bar{y}$, then the estimated prior distribution is taken to be degenerated at $\theta = \bar{y}$.

The EB estimate for θ_i is the posterior mean, with plug-in parameters given by [14]. The posterior distribution for the gamma-Poisson model is also a gamma distribution with shape and rate parameters $(\alpha + y_i)$ and $(1 + \beta)$. Because this posterior gamma distribution has mean $(\alpha + y_i)/(1 + \beta)$, the EB estimate follows as:

$$\hat{\theta}_i^{EB} = \hat{B}\hat{\mu} + (1 - \hat{B})y_i = \hat{B}\bar{y} + (1 - \hat{B})y_i \quad [15]$$

where $\hat{B} = \hat{\beta}/(1 + \hat{\beta})$. The confidence interval for $\hat{\theta}_i^{EB}$ is based on the posterior variance

$$V(\theta_i | y_i, \mu, \beta) = (\mu\beta + y_i)(1 + \beta)^2 \quad [16]$$

Again, a plug-in estimate for $(\hat{\mu}, \hat{\beta})$ is used.

EB Beta-Binomial Model

The beta-binomial model has been used in the study of criterion-referenced testing for various purposes such as the determination of test length (Novick and Lewis, 1974) and cutoff scores (Huynh, 1977). A criterion-referenced test consists of a sample of n items drawn from a domain of items, developed from a framework of learning objectives. The number correct for the i th student is used to infer the student's proficiency, assumed unobservable. Denote the proficiency of the i th student by θ_i . Then, (1) states that θ_i , $i = 1, \dots, I$, varies across students, following a beta distribution, and (2) states that, given proficiency θ_i , the number of correctly answered questions y_i follows a binomial distribution with parameters (n, θ_i) , where n is the total number of questions on the test. The beta-binomial model can be expressed by the following two equations:

$$p_{Beta}(\theta_i | \alpha, \beta) = \frac{\theta_i^{\alpha-1}(1-\theta_i)^{\beta-1}}{\text{Beta}(\alpha, \beta)}, \quad 0 \leq \theta_i \leq 1 \quad [17]$$

where $\text{Beta}(\alpha, \beta) = \frac{\Gamma(\alpha)\Gamma(\beta)}{\Gamma(\alpha+\beta)}$ is the beta function; and

$$P(Y_i = y_i | \theta_i) = \binom{n}{y_i} \theta_i^{y_i} (1 - \theta_i)^{n-y_i}, y_i = 0, 1, \dots, n \quad [18]$$

The marginal distribution of y_i is the so-called beta-binomial density:

$$P(Y_i = y_i) = \frac{1}{\text{Beta}(\alpha, \beta)} \binom{n}{y_i} \frac{\Gamma(\alpha + y_i)\Gamma(\beta + I - y_i)}{\Gamma(\alpha + \beta + I)} \quad [19]$$

To estimate the global-structure parameters, we resort to the method of moments, because ML does not generally lead to a closed form. Much as in the case of gamma-Poisson, we benefit from a reparameterization from (α, β) to (μ, λ) , where $\mu = \alpha/(\alpha + \beta)$, and $\lambda = \alpha + \beta$. The parameter μ is the mean of the beta distribution, whereas the parameter λ suggests an effective sample size for the prior distribution, decreasing with variance. If V denotes the variance of the beta distribution, then $V = \mu(1-\mu)/(\lambda+1)$. Note that, if a binary variable Y has mean μ , then with a sample size n the standard error for the MLE for μ is $V = \mu(1-\mu)/n$. Hence, $\lambda + 1$ plays the role of sample size. The moment estimates for (μ, λ) are:

$$\hat{\mu} = \frac{\sum_{i=1}^I y_i}{nI} \text{ and} \quad [20a]$$

$$\hat{\lambda} = \frac{\hat{\mu}(1 - \hat{\mu}) - s^2}{s^2 - \frac{\hat{\mu}(1 - \hat{\mu})}{I}} \quad [20b]$$

where $s^2 = \frac{1}{I} \sum_{i=1}^I (\frac{y_i}{n} - \hat{\mu})^2$.

The posterior distribution $\theta | y_i, \mu, \lambda$ is also a beta distribution with α, β replaced by $\alpha + y_i$ and $\beta + n - y_i$, respectively. Therefore, the mean of the posterior distribution is $\alpha + y_i/(\alpha + \beta + n)$, and after plugging in the estimates from above the EB estimate for individual θ_i is estimated as:

$$\hat{\theta}_i^{EB} = \hat{B}\hat{\mu} + (1 - \hat{B})\frac{y_i}{n} \quad [21]$$

where $\hat{B} = \hat{\lambda}/(\hat{\lambda} + n)$. The shrinkage factor \hat{B} is a function of the relative strength of the sample sizes from global and local sources, with the global source providing an effective sample size $\hat{\lambda}$. When sample sizes vary across units, so does shrinkage. The confidence interval for $\hat{\theta}_i^{EB}$ is based on the estimated posterior variance:

$$V(\theta_i | y_i, \hat{\mu}, \hat{\lambda}) = \frac{(y_i - \hat{\mu}\hat{\lambda})(n - y_i + \hat{\lambda} - \hat{\mu}\hat{\lambda})}{(n + \hat{\lambda})2(n + \hat{\lambda} + 1)} \quad [22]$$

Generalization and Extensions

These instances of the EB method are special cases in which the prior and conditional distributions form conjugate pairs, leading to mathematically tractable marginal distributions. Furthermore, these are examples of the parametric EB approach. **Figure 1** is examined for extension of the approach. Starting from the top, the prior density $g_\eta(\theta)$ that provides the global information assumes a specific parametric form with hyperparameter η . In the normal-normal case, $g_\eta(\theta)$ is the normal distribution, with η assumed known in the first and $\eta = \mu$ in the second case. The conditional distribution for y_i is often assumed to

follow a separate parametric function $f(y | \theta)$. Typically, EB-based inferences target the unobserved individual θ_i , to which end there are the following steps:

1. Form the marginal distribution of the observed data

$$p(y) = \int g_\eta(\theta) f(y | \theta) d\theta, \quad [23]$$

where $g_\eta(\theta) = g_\eta(\theta_1) \times \dots \times g_\eta(\theta_I)$, and $f(y | \theta) = f(y_1 | \theta_1) \times \dots \times f(y_I | \theta_I)$.

2. Using [23], estimate the hyperparameter η using, for example, maximum likelihood; leading to $\hat{\eta}$.
3. Form the posterior distribution $p(\theta_i | y_i, \eta)$ using Bayes' theorem, and plug $\hat{\eta}$ into the posterior:

$$p(\theta_i | y_i, \eta) = \frac{p(y_i | \theta_i) g_\eta(\theta_i)}{\int p(y_i | \theta_i) g_\eta(\theta_i) d\theta_i} \quad [24]$$

4. Form the EB estimate using step (3): $\hat{\theta}_i^{EB} = E(\theta_i | y_i, \hat{\eta})$.
5. Form confidence intervals of $\hat{\theta}_i^{EB}$, using variance function $V(\theta_i | y_i, \hat{\eta})$.

Several observations can be made. First, if the distributions $g_\eta(\theta)$ and $f(y | \theta)$ do not form a conjugate pair, the solutions for $\hat{\eta}$ and $\hat{\theta}_i^{EB}$ may require numerical procedures, as will their corresponding precision measures. The expectation–maximization (EM) algorithm (Dempster *et al.*, 1977) is often used for estimating the hyperparameters. Second, from a Bayesian perspective, the EB approach has stopped short of accommodating uncertainty associated with hyperparameter estimation. This issue is discussed within the next example. Third, the parametric EB approach with regard to $g_\eta(\theta)$ and $f(y | \theta)$ can be extended by approached $g_\eta(\theta)$ nonparametrically instead. The pioneering work of Robbins (1955) established a theoretical foundation. In educational measurement, however, a more common extension is by incorporating regression models into either the prior $g_\eta(\theta)$, the conditional $f(y | \theta)$, or both. This is exemplified in the next section.

EB analysis for the NAEP

This example is chosen for two reasons. First, NAEP is a highly visible educational assessment tool in the United States, and reports are of great public interest because they are often cited to support specific educational and political agendas. Second and more technical, the statistical models used (Beaton and Johnson, 1992) exhibit rich features, useful for illustrating both the power and limitations of the EB approach (*cf.* Scott and Ip, 2002).

The NAEP survey measures the academic performance of US students cross sectionally and over time. Mandated by the US Congress and funded by the federal government, NAEP reports academic achievements and identifies differences in performance between student-population subgroups categorized by demographic and

other contextual variables (e.g., time spent watching television). Unlike individual achievement tests (e.g., Scholastic Aptitude Test (SAT)), NAEP reports on overall performance of subgroups or aggregates of students. While NAEP calculates individual proficiency scores and associated student sampling weights using draws from students' estimated ability distributions, it does not report individual student performance – this being prohibited by law. The NAEP approach for analyzing student data consists of two interlinked statistical models. The first captures local information with regard to a student's academic performance based on his/her responses to cognitive items on a given subject matter. The second model creates a global structure, allowing sharing of information across students and schools. Denote by $\theta_i = (\theta_{i1}, \dots, \theta_{is})$ the subscale proficiency level vector for student i , by x_i a vector of contextual and background variables, and by y_{ij} the response to the j th item (correct = 1, incorrect = 0). For reading assessment, there are three subscales ($S = 3$): reading for literary experience, for information, and to perform a task. The global model states that:

$$\theta_i \sim \text{MVN}(\beta^T x_i, \Sigma) \quad [25]$$

where β groups regression coefficients and Σ is a variance–covariance matrix. Such a specification allows the different subscales to be correlated. The local model for individual students is based on the item-response model (IRT; Lord, 1980). For dichotomous items, the three-parameter logistic IRT model given below is used for scaling student responses:

$$\begin{aligned} f(y_{ij} | \theta_{is(j)}) &= P(Y_{ij} = 1 | \theta_{is(j)}) \\ &= c_j + \frac{(1 - c_j)}{1 + \exp(-1.7a_j(\theta_{is(j)} - b_j))} \end{aligned} \quad [26]$$

where $\theta_{is(j)}$ is the proficiency for subscale s to which item j belongs, $j = 1, \dots, J_s$ and a_j, b_j, c_j are the item discrimination, difficulty, and guessing parameters, respectively. Factor 1.7 in [26] is a historical artifact relating the logit and probit links. To focus on the EB structure, the following simplifications are made: all items are dichotomized; their item parameters are *a priori* determined through a standard IRT-based calibration procedure and will be treated as known; and the student sampling weights are uniform.

The EB approach is based on [25] and [26], and hyperparameter η contains β and Σ . Function $f(y_i | \theta_i)$ is now multivariate because y_i is the vector of the binary responses J_{is} for student i at the items of subscale s . Assuming local (conditional) independence, that is, that the item responses for each subscale are independent given proficiency level θ_{is} , then $f(y_i | \theta_{is}) = f(y_{i1} | \theta_{is}) \times \dots \times f(y_{iJ_{is}} | \theta_{is})$. Further assuming that the responses between subscales are independent, the overall response function, therefore, is the product over all subscales. Because of multiple test

forms, the number of items answered per subscale is student dependent. The likelihood is based on these observed factors only. This approach is valid, assuming that the missing responses are missing at random (Little and Rubin, 1987).

The parameters β and Σ are estimated by marginal maximum likelihood, the core of which is an EM algorithm (Mislevy *et al.*, 1992). A standard EB approach would use the plug-in estimate for the regression coefficients β on students' background variables and Σ , and for the variance-covariance matrix for the subscales, to produce the expected value of student subscale proficiency θ_{is} given the observed responses and the plug-in estimates.

Bayesian shrinkage for θ_{is} tends to pull the estimate of proficiency purely based on an individual's responses toward the mean of the student's subgroup – defined by the levels of x_i . Beaton and Johnson (1990) and Mislevy (1991) found asymptotic bias in statistics involving background variables that are not conditioned on, the magnitude of which relates to the extent to which responses may account for the unobserved proficiency θ_{is} and the degree to which the unconditioned background variables are explained by their counterparts in the model. Thus, the EB estimate with conditioning variables tends to mitigate potential bias by about 10% across many NAEP analyses using the unconditional model (Mislevy, 1991).

Figure 3 depicts the effect of Bayesian shrinkage. Here, standard IRT procedures are applied to the 1996 Long Term Trend Reading Data, based on responses to 22 items on a single scale for $N = 918$ students and assuming that the prior distribution is standard normal. The S-shaped curve shows that the absolute values of the EB estimates are smaller than their ML counterparts and that the shrinkage effect is larger for values that are farther away from the overall mean (zero).

While the EB estimate using the conditioning variables limits bias and, generally, outperforms ML, the measures for uncertainty associated with it (e.g., standard error), are

underestimated – especially when based on the assumption that the plug-in estimates contain no measurement errors. There are many correction procedures – at individual and at population levels. NAEP adopted a methodology – called plausible value – based on multiple imputation (Rubin, 1987). The plausible-value method is implemented through several steps (Johnson *et al.*, 1996):

(P1) Draw a value of (β, Σ) from a normal approximation to the posterior $p(\beta, \Sigma | \mathbf{y}, \mathbf{x})$, denoted by $(\tilde{\beta}^{(1)}, \tilde{\Sigma}^{(1)})$ [the operational NAEP procedure keeps Σ fixed and draws only for β];

(P2) Based on this, compute the mean and variance-covariance matrix for the posterior distribution of the proficiencies vector $p(\theta_i | \mathbf{y}, \mathbf{x}, \tilde{\beta}^{(1)}, \tilde{\Sigma}^{(1)})$;

(P3) Draw a value for $\theta_i(1)$ using a multivariate normal approximation of $p(\theta_i | \mathbf{y}, \mathbf{x}, \tilde{\beta}^{(1)}, \tilde{\Sigma}^{(1)})$, with mean and variance-covariance calculated from (P2); and

(P4) Repeat steps (P1) through (P3) M times.

In NAEP, $M = 5$. The total sampling variance for the proficiency estimate – or of any statistic based on the posterior $p(\theta_i | \mathbf{y}, \mathbf{x}, \beta, \Sigma)$ – is given by the sum of the average sampling variance over the M sets of plausible values $\theta_i^{(m)}$, $m = 1, \dots, M$, and the variance among the M estimates. The former – the so-called within-imputation variance – is meant to be an approximation to the posterior variance $V(\theta_i | \mathbf{y}, \mathbf{x}, \beta, \Sigma)$. The latter – the between-imputation variance – is designed as a correction for the uncertainty due to not directly observing the θ_{is} and is:

$$G = \sum_{m=1}^M \frac{(\theta_{is}^{(m)} - \bar{\theta}_{is})^2}{M-1} \quad [27]$$

where $\bar{\theta}_{is}$ is the mean of $\theta_{is}^{(m)}$. The final estimate of the variance of $\hat{\theta}_{is}^{EB}$ is:

$$V(\hat{\theta}_{is}^{EB}) = \hat{V}(\theta_i | \mathbf{y}, \mathbf{x}, \beta, \Sigma) + (1 + M^{-1})G \quad [28]$$

Hence, this approach aims at conducting proper inference for student proficiency both at the individual and population

Figure 3 Maximum likelihood estimates and empirical Bayes estimates of student proficiencies in NAEP Long Term Trend Reading Assessment.

levels by enhancing the EB approach so that it approximates a fully Bayesian approach. It is argued that the fully Bayesian approach takes into account the various sources of uncertainty – including those derived from using a plug-in estimate for (β, Σ) .

For illustration, the 1998 eighth-grade national reading assessment ($N = 11\,051$) is analyzed and **Table 2** provides the mean and the within- and between-imputation variances – $M = 100$. For more details and ramifications, see Scott and Ip (2002). Here, the between- and within-imputation variances are comparable – implying that the second source of variability increases the standard error by about a factor $\sqrt{2} = 1.4$, relative to EB.

Other Educational Applications and Conclusion

The EB approach relies on a two-level formulation of how data across statistical units arise, and offers a rigorous theoretical framework for using global information gleaned across individual units for informing local estimates – which are only based on responses from a specific individual. In contrast to a fully Bayesian approach, EB emphasizes estimating prior distributions from the data. From a modeling perspective, the EB approach is amenable for (non)linear multilevel modeling – especially when inference targets unobservables such as proficiencies or teaching skills.

The range of EB applications is wide. Braun (2006) applied the approach to analyze important performance predictors on the Graduate Record Examination (GRE) across various college departments. He used a normal-normal model in which the student's first-year grade point average (GPA) is treated as the response y , the student's GRE scores as predictors, and regression coefficients as unobservables of interest. The global structure is a regression model incorporating department-level covariates.

Meta-analyses for educational studies also make use of EB; information is combined across studies, and the effect size of a specific classroom intervention from study i can be conceptualized as an unobserved variable θ_i . Information is borrowed across studies through the specification of a global data-generating structure (Hedges, 1987; Raudenbush and Bryk, 1985).

For evaluating teacher and school effectiveness, EB was applied to value-added models – a collection of models that attempts to delineate, from a return-on-investment perspective, the effectiveness of school systems and personnel based on the complex interactions among student characteristics, school effects, community characteristics, school district policies, etc. Information is borrowed from teacher assessment results for inferences on a school system or employee, and regression models are incorporated at global and local levels to control for interaction effects. McCaffrey *et al.* (2004) review value-added models and related EB methodologies. Multi-level growth-curve modeling for assessing educational-intervention effects (Plewis, 2000; Pituch, 2001) is another versatile application area. Typically, a growth curve from an individual student contains only few data points, but strength can be borrowed across students to stabilize individual growth curve estimates. This conventionally results in individual curves shrunk toward a smoother, population-based growth version. Another classic EB example is in the study of school effects through hierarchical linear modeling (Raudenbush, 1986). The author sets up a multi-level hierarchical model with covariates at individual and school levels.

The EB approach capitalizes on using information from higher-level statistical units to enhance estimates at individual level, without subjective input on prior distributions. From a Bayesian perspective, the EB approach is regarded as an approximation to a fully Bayesian approach. The general notion of borrowing information

Table 2 EB mean, within-, and between-imputation variance for 1998 NAEP reading proficiency by subgroup

$M = 100$ plausible values are used in this calculation.

The last four subgroups are categories from parent education: less than high school, high school, post high school, and college.

across statistical units is powerful and extends readily to many innovative applications. A recent example is in simultaneous multiple hypothesis testing (Efron, 2004). Unsurprisingly, EB has been regarded as one of the most important advances in the field of statistics since World War II (Efron 2007).

Glossary

Constructivist evaluation – Seeks information based on stakeholders' "constructions" of an evaluation question or issue in a process in which evaluator and stakeholders communicate with each other, engaging in dialectical process aimed at achieving as much consensus as possible among the varying perspectives of stakeholders.

Deliberative democratic evaluation – Is inclusive (all relevant interests are represented), dialogical (stakeholders and evaluators engage in dialogue), and deliberative (conclusions emerge from reasoning, reflection, and debate).

Empowerment evaluation – Is a collaborative group activity which employs evaluation concepts, techniques, and findings, to help people help themselves in providing a program.

Evaluation model – Is a term used to describe the main concepts, structure, and procedures that are used to guide an inquiry designed to assess an object, program, practice, activity, or system to arrive at defensible descriptions and judgments.

Ideographic inquiry – Focuses on the uniqueness of individuals or events, describing them in terms of their individual attributes and interrelationships between attributes.

Interpretative assumptions – Underlie approaches to evaluation that incorporate the perspectives of participants and in which the evaluator recognizes the influence that his/her role can have on the evaluation process.

Nomothetic inquiry – Has as its aim the discovery of general laws or principles applicable to all individuals (or individuals in specified categories).

Responsive evaluation – Is oriented toward program activities rather than program intents, responds to audience requirements for information, is based on observation and reaction rather than on formal measurement procedures, and takes account of different value perspectives in reaching conclusions.

Scientific management movement – Is the term applied to efforts early in the twentieth century to apply scientific principles to the management of industry, the division of labor, and the training and

supervision of employees (sometimes called Taylorism, named for its main exponent Frederick Taylor).

The term evaluation research has appeared in the educational literature from time to time, at least since the 1970s. There is, however, lack of agreement on its definition. This may be because the activities represented by the term have become more disparate over the years to reveal major differences in underlying assumptions, purposes, procedures, and intended uses. Or it may arise from problems in distinguishing research that can be described as evaluative from other types of educational research.

A definition of evaluation research must take account of the fact that the term represents the intersection of two activities: evaluation and research (see **Figure 1**). Not all evaluation has a research component, and not all research involves evaluation. With this in mind, together with a consideration of the activities to which the term is usually applied, evaluation research may be defined as a form of disciplined and systematic inquiry that is carried out to arrive at an assessment or appraisal of an object, program, practice, activity, or system, with the purpose of providing information that will be of use in decision making.

Basing evaluation research on disciplined and systematic enquiry, which usually involves the methodology of the behavioral or social sciences, is an attempt to control bias and to reach conclusions that will be defensible and open to scrutiny. This distinguishes evaluation research from the evaluation activity of everyday life in which objects or events are judged as good or bad, adequate or inadequate, of good quality or of poor quality, frequently in an intuitive, informal, impressionistic, and possibly biased way. Evaluation research also differs from activities that involve educational evaluation but not research, such as the application of the technology of testing (e.g., to diagnose student learning difficulties, to select students for further education).

The fact that evaluation research is carried out to arrive at an assessment or appraisal is usually interpreted as implying that, compared to basic, pure, or fundamental research (which has as its objective the creation of knowledge), it has a practical orientation. More specifically, it is designed to obtain information that can be acted on in policy formation or management decisions.

This interpretation is reinforced by the fact that evaluation research is a highly politicized activity. The decision to

Figure 1 The intersection of evaluation and research.

carry out an evaluation is itself political, and its findings are likely to enter an immensely complex web of social decision making to which many stakeholders may have an input. Furthermore, when the object of an evaluation is an intervention program, results can threaten the conceptual basis of the program, undermine the reputation and careers of those involved, and affect jobs and staff morale (Weiss, 1991). Add to these conditions the fact that research and evaluation findings may challenge traditional views, vested interests, or current fashions, and the reason why findings have not had the same impact on practice as research in medicine or agriculture becomes clearer.

Program Evaluation

Much early evaluation research focused on aspects of a service or ongoing cyclical activities, such as teaching methods and teacher education, or a single variable, such as class size. Since the 1960s, the evaluation of programs (a rather loose term to describe a coordinated well-specified set of activities directed at achieving goals, often involving the design and implementation of new approaches to educational provision or service configuration) achieved considerable prominence. A program may stand alone, it may be implemented in a single site, or it may be large scale, complex, and implemented in multiple sites.

The components of a program evaluation are encapsulated in Stufflebeam's (2003) CIPP model, which is presented as a comprehensive framework for conducting and reporting evaluations. Corresponding to the letters in the acronym CIPP, the model's core concepts are context evaluation (the assessment of needs, problems, and opportunities as bases for defining goals and priorities, and for judging the significance of outcomes); input evaluation (identifying resources and determining if they are adequate); process evaluation (an ongoing check on the implementation of planned activities); and product evaluation (the identification of intended and unintended outcomes, both to help keep the process on track and to determine effectiveness).

A distinction is frequently drawn between the formative and summative evaluation of programs. Formative evaluation is designed to support program improvement and is normally requested by, or carried out by, an agent that is in a position to effect improvement. Summative evaluation, on the other hand, is carried out for, or by, decision makers who need the conclusions of an evaluation for reasons other than development.

Program evaluation is not synonymous with evaluation research. In **Figure 1**, it is depicted as a subset of both evaluation research and nonresearch evaluation activity. While some program evaluations involve a research methodology, others, such as educational connoisseurship, are based on expert judgment. Furthermore, much activity that would be considered evaluation research involves variables (e.g., class size) rather than programs.

A program evaluation will have as its primary objective a description of the functioning and effectiveness of a specific program. However, there is also the expectation that a synthesis of the findings of a number of evaluations could provide evidence that would justify more widespread application, providing guidance for decisions and reforms (see, e.g., What Works Clearinghouse at the Institute of Education Sciences, US Department of Education; Best Evidence Encyclopedia at the Center for Data-Driven Reform in Education at the Johns Hopkins University). It has been argued that support for generalization will be enhanced if evaluations are based on a framework that provides a theoretical rationale for a program (why treatments and implementation processes were chosen) and a description of the mechanisms (often complex) through which program activities are understood to have contributed to intended outcomes (Chen, 1990).

Methodology of Evaluation Research

The methodology of evaluation research is usually categorized as quantitative or qualitative. Quantitative methods emulate as far as possible the logic and methodology of the physical sciences, while qualitative approaches are more attuned to the complexities of the human condition.

Quantitative Methods

Quantitative measures include standardized tests, questionnaires, and a variety of rating scales. The classic quantitative approach also employs an experimental design in which participants are randomly assigned to treatment and control groups. Following the implementation of a treatment, criterion measures are administered and, because participants have been randomly allocated, observed differences in outcome between groups can reasonably be attributed to the differential effect of the treatment. Internal validity is established if evidence supports

the conclusion that experimental treatments were effective in a specific experimental instance. Further evidence, however, is required to establish if the effect can be generalized to other situations (external validity). A frequently cited experimental study was carried out in Tennessee, in which more than 6000 kindergarten students in 329 classrooms were randomly assigned to one of three conditions: small classes (13–17 students), regular classes (22–26 students), and regular classes with a full-time teacher aide. Students remained in their classes from kindergarten to the end of third grade, at which point a comparison of the groups on tests of reading and mathematics revealed a favorable effect of small class size (Finn and Achilles, 1999).

Large-scale experimental studies are rare because of practical and ethical difficulties in randomly assigning participants to treatment and control groups in real-life situations. In their place, a range of quasi-experimental designs, in which treatment is manipulated and outcomes are observed, but which do not involve random assignment to conditions, may be used. For example, if a comparison group is involved, it will be chosen to be as similar as possible to the treatment group (in particular, attending to the possibility of selection bias), information on variables of interest is obtained before and after treatment (pretest and posttest), and covariance analysis or regression may be used to adjust posttest measures, as long as initial differences are not large.

Surveys, a further form of quantitative inquiry, are frequently employed to assess the achievements of students in an education system using standardized tests. While they do not involve a comparison group, it is usually possible to compare the achievements of subpopulations (e.g., males and females; students in urban and rural locations). The best-known example of a survey was commissioned by the US government in the mid-1960s to describe lack of equal educational opportunities in the public school system. The study found that, with some exceptions, minority group students through the grades had lower achievement scores than white students. While the schools attended by minority students also had poorer resources, variation in facilities and curricula accounted for relatively little variation in student achievement (Coleman *et al.*, 1966). The then commissioner of education, Harold Howe II, noted that the US Office of Education would determine how it could use the results to enhance educational opportunities.

Qualitative Methods

It has been argued that, while quantitative studies attempt to match the standards and objectivity of the physical sciences, they fail to take account of the uniqueness and complexities of human behavior. Qualitative studies address this issue when they adopt a naturalistic posture, which recognizes the phenomenological character of the evaluation context,

attempts to represent a variety of perspectives reflecting multiple realities, and allows understanding to emerge.

Qualitative methods are not easily defined, partly because they are derived from several research traditions, which include ethnography, document analysis, interviews, participant observation, and deliberations of focus groups. Data are frequently collected in the context of a case study, which has a number of features: the holistic in-depth examination of a program and of its internal workings; the collection of information from a multiplicity of sources; and the development, testing, and replication of theoretical propositions to arrive at generalizations.

Mixed Methods

On the assumption that methods can be complementary, many commentators encourage flexibility in deciding on methodology, and propose the use of a mixture of quantitative and qualitative methods. It is argued that examining a phenomenon from a variety of perspectives (involving, e.g., multiple operationalization of key constructs, multiple measures, and multiple investigators) facilitates a process known as triangulation (a term borrowed from surveying), in which combining a variety of types of data serves to illuminate, confirm, or challenge conclusions. Quantitative methods will usually be chosen to provide standardized replicable findings on large data sets, and qualitative methods to elucidate the cultural context, themes, dynamics, and internal relationships of programs. Creswell (2003) provides guidelines for the use of mixed methods relating to priority (which approach will be dominant), implementation (in which a clear sequence of activities is prepared; e.g., a survey followed by ethnographic exploration of identified trends), integration (how different types of data will be combined), and theory (the philosophical assumptions underlying methods). While a consideration of philosophical assumptions must raise doubts about the appropriateness of using methods in a study which are based on radically different conceptions of reality, of the nature of knowledge, and of the relationship between evaluator and what is evaluated, the use of mixed methods is increasing.

Early Development of the Field of Evaluation Research

It was not until toward the end of the nineteenth century that developments in the emerging behavioral sciences, emulating the logic and methodology of the physical sciences, provided models for empirical investigation that could form a basis for educational research. At the time, a distinction was drawn between a nomothetic approach, with the aim of establishing general laws governing human and social behavior (leading to explanation of an event as an instance of a law) and an ideographic approach which focused on the

unique elements of individual phenomena (leading to understanding). The distinction resonates to this day in the views of proponents of quantitative experimental procedures and proponents of qualitative naturalistic inquiry.

Evaluation research and its development have been predominantly American-based. In light of this, it is not without interest that the origins of empirical research from which evaluation research later developed were in Europe – in Germany (where Wundt established his laboratory), in France (where Binet devised a method of mental measurement), and in Britain (where Galton, Fisher, and Spearman laid the foundations of statistical analysis). However, what is generally regarded as the first formal evaluation (though it was not called that at the time) was carried out toward the end of the nineteenth century in the United States when Joseph Rice set the scene for the paradigm that was to dominate evaluation research for much of the twentieth century in his study of the effects of instructional time on students' spelling ability. The study was marked by two features: the use of quantitative measures of students' achievements, and a comparative research design (in which the amount of time devoted to spelling instruction was varied).

The early decades of the twentieth century saw the quantitative approach flourish, mainly in the form of surveys of student achievement and school conditions. Under the influence of the scientific management movement, studies were carried out to identify school and teacher efficiency, to diagnose specific system weaknesses, to standardize curriculum practice, to evaluate innovations, and to assess the overall performance of a local education system.

Ralph Tyler, who is generally regarded as laying the foundations of evaluation research as we now know it, signaled two important developments in his 8-year study (Smith and Tyler, 1942). First, evaluation was conceptualized as involving a comparison of intended and actual student achievement, obviating the need for costly and disruptive comparisons between experimental and control groups. Second, objectives of programs were defined in behavioral terms, and formed the basis of instrument development.

The role and extent of evaluation research changed radically in the late 1950s and 1960s as a result of two initiatives of the United States federal government. First, in the wake of the launch of Sputnik in the Soviet Union (in 1957), government responded to lobbying for reform by providing funds to support the introduction of new curricula to schools with the objective of improving achievement, particularly in mathematics, science, and foreign languages. Second, in response to concern about equality of educational opportunity, a broad array of initiatives designed to raise student achievement in socially and economically disadvantaged communities was launched in the war on poverty. The fact that the initiatives had associated requirements for evaluation gave a major boost to evaluation

research. The response was an increase in research activity which favored the use of experimental/randomized or quasi-experimental designs as these were perceived to have the greatest potential to determine if programs were meeting goals, to study cause-effect relationships, and to provide policy guidance. There are many examples of short- and long-term evaluations of school curricula and of intervention programs to serve children in disadvantaged areas in the United States.

Evaluation activity throughout the world, though not as extensive as in the United States, paralleled or was influenced by American practice. During the 1960s and 1970s, for example, as in the USA, evaluations of social and educational interventions and programs were carried out in European countries. Compared to practice in the USA, however, qualitative methods were preferred to quantitative methods. From the 1980s onward, under pressure from the European Economic Community (later the European Union), the focus in evaluation shifted to results and issues relating to quality, accountability, and effectiveness. In many countries, the methodology of evaluation research came to be seen as having a role to play in the management of public affairs, serving to identify performance targets, indicators, and outcomes.

The Professionalization of Evaluation Research

As demand for evaluation by government agencies grew through the 1960s and 1970s, the term evaluation came into common use. Professional organizations with a focus on program evaluation were formed, publications (books and journals) dealing with the topic appeared, and courses in evaluation were established in universities. Evaluation was developing as a field distinct from, but related to, the older disciplines of research and testing.

A variety of evaluation models emerged which reflected greater appreciation of the complexity of evaluation activity, together with greater understanding of how it fitted into organizational and bureaucratic decision making. Increased recognition was accorded the role of political factors and the competing interests of stakeholders, and how they might be accommodated. New conceptualizations of evaluation began to emerge as a range of issues were addressed: the evaluation of program goals; the identification of unintended as well as intended outcomes; descriptions of program inputs and program strategies, and how they might change over time; monitoring of variation in implementation and service delivery; and descriptions of the characteristics of participants and how they responded to their experiences.

Development, however, faltered as social science research in general suffered a set-back in funding in the 1980s following a change in political climate (particularly

in the USA and the UK) which signaled increased interest in measuring the outcomes of programs or systems, often in the context of accountability, quality assurance, and the management of resources. The most outstanding examples of this development are to be found in assessments of student achievement at state level in the USA (e.g., the mandating of academic learning standards and the assessment of student achievement with respect to the standards), at national level (e.g., the US National Assessment of Educational Progress), and at international level (e.g., the Organization for Economic Cooperation and Development (OECD) Program for International Student Assessment (PISA)). Such government-sponsored activities, which are a feature of education systems throughout the world since the 1990s, now account for a considerable amount of the financial resources available for research in education. They resemble activity in the early decades of the twentieth century, except that they are carried out at state, national, and international, not local, level.

Quis Custodiet?

The question posed by the first/second-century Roman satirist Juvenal, *quis custodiet ipsos custodes?* (who will watch over the guardians?) has frequently been asked in the context of the exercise of power, and so is appropriate in the case of evaluation. Given the power that evaluators possess, and the potential for their findings to impact on a variety of individuals, we may ask what procedures are available to monitor or influence the conduct of an evaluation. Four such procedures can be identified. Their identification, however, should not be taken to imply that they are widely used or necessarily effective.

Conformity to Standards

A number of sets of principles or standards that should govern evaluation practice (in particular, program evaluation) are available. Principles established by the American Evaluation Association (AEA) specify that (1) inquiry should be systematic; (2) evaluators should be competent; (3) the integrity of the process should be ensured; (4) the security and dignity of all involved should be respected; and (5) account should be taken of the public interest (Shadish *et al.*, 1995).

While the AEA principles were directed at evaluations across a variety of government and social service sectors, the focus of the Joint Committee on Standards for Educational Evaluation (1994) was on education. The joint committee specified 30 standards categorized under four headings: utility (evaluations should be informative, timely, and influential), feasibility (evaluations should be realistic, prudent, diplomatic, and cost effective), propriety (evaluations should be lawful and ethical), and

accuracy (evaluations should provide accurate information about the merits of a program).

Meta-evaluation

A meta-evaluation is an evaluation of an evaluation designed to assess its quality and to help users decide whether or not to accept and act on its conclusions. While a variety of procedures have been used for this purpose, including consultants' evaluations, secondary analyses of data, and multiple replications, the most systematic description of the procedures required for meta-evaluation has been provided by Stufflebeam (2000). These specify interaction with the meta-evaluation stakeholders, identification of a qualified meta-evaluation team, a review of available information, the collection of new information if required (e.g., in interviews or surveys), a judgment of the evaluation's adherence to standards (e.g., the standards of the Joint Committee on Standards for Educational Evaluation), and the preparation and submission of reports.

Involvement of Stakeholders in Designing and Monitoring an Evaluation

The involvement of stakeholders in planning and designing an evaluation and in monitoring its progress (e.g., in a steering committee) has been proposed as a way of ensuring that some control of an evaluation is assigned to those who will be affected by its findings. It has the further advantage of providing the opportunity for the perspectives and values of stakeholders to be addressed and reflected, while increasing the likelihood that the findings will be acted on. Whether only a select representative group of users or all relevant interests should be represented is a matter of debate.

Involvement of Stakeholders in the Conduct of an Evaluation

A step beyond involving stakeholders in determining the main features of an evaluation and monitoring its implementation is to consider their perceptions, values, and interests as central, and to respond to them in reporting findings, as proposed, for example, in the deliberative democratic evaluation of House and Howe (1999) and the responsive evaluation of Stake (1976). More extreme views regarding power in an evaluation have been expressed by Guba and Lincoln (1989) who proposed that an evaluation report should comprise an interpretation of the meanings that stakeholders construct in the course of an evaluation (constructivist evaluation) and by Fetterman (1994) who saw the evaluator as having a merely technical role in a process in which stakeholders are empowered to carry out their own evaluation, shaping its direction, suggesting solutions to problems, and ultimately taking an active role in effecting social change (empowerment evaluation).

Conclusion

Developments in evaluation research during the twentieth century have resulted in a much richer view of its complexity, and issues that might have been considered relatively straightforward even in the middle of the century no longer seem so. The field also has fractured, however, as conflicts over theory and methodology emerged, relationships between researcher and object of research were reconstructed, and realist assumptions were challenged by interpretative ones.

Meanwhile, in response to the needs of bureaucrats, the focus of evaluation research was being narrowed to address managerial concerns, to help define performance, to set targets and performance indicators, to use student testing as a policy lever, and to base resource-allocation decisions on performance information. From this perspective, there is little interest in monitoring program implementation or in determining why some practices or institutions are effective, and others not. All one needs is to be able to identify the satisfactory and unsatisfactory, often cloaked in terms of quality and lack of quality, with statistical data to support the judgment. A competitive market and threats or promises of sanctions should lead to raised expectations for students, improved teaching, and an increase in students' test scores. In this situation, many of the activities and issues associated with evaluation research described in this article will be redundant. As for the future, the wide range of conflicting interests and ideologies, both within and outside the evaluation community, suggest that major efforts will be required if evaluation research is to develop to the satisfaction of evaluators working in the tradition of social science research, while at the same time fulfilling the role always envisaged for it – the provision of information that will serve the needs of decision makers.

Exploratory Data Analysis

A Unwin, University of Augsburg, Augsburg, Germany

© 2010 Elsevier Ltd. All rights reserved.

Introduction

Exploratory data analysis (EDA) is different from classical statistics. It is not about fitting models, parameter estimation, or testing hypotheses, but is about finding information in data and generating ideas. The data being studied may be an independent random sample from a population of interest, but they could just as easily be a collection of data whose provenance is not fully known. EDA is valuable for generating hypotheses, while classical methods are important for testing them.

Researchers and analysts have always been carrying out EDA, even if they did not use that name for it. EDA involves looking at the data in many different ways to gain insights, and incorporating domain knowledge about the data into the analyses.

What is EDA?

EDA is an approach, a methodology rather than a set of techniques. Tukey suggested that carrying out a data analysis meant acting like a detective. You have a general goal in mind, but you should remain open to all kinds of evidence and you cannot be sure in which direction that evidence might lead you. On the other hand, he regarded carrying out classical statistical analyses as acting more like a judge. Hypotheses have to be clearly defined in advance, only certain kinds of evidence are permissible, and there are very specific rules for proceeding. All that this means is that EDA is more of an art than a science. There are general principles that should be followed, but not many formal procedures. It is flexible and data driven rather than regulated and hypothesis driven. Each person will carry out a data analysis in a different way – though they should all discover the same information.

Most introductory statistics textbooks include a discussion of descriptive statistics: usually some standard graphics (e.g., histograms and scatter plots), some tables (frequency and contingency), and summary statistics of location (mean, median, and mode) and of variability (variance, range, and standard deviation). Whether more than this (or less!) is covered depends on the book. The emphasis is on description and not on induction. The graphics and statistics are used in a passive rather than an active way. EDA employs the tools of descriptive statistics, but with the aim of extracting information. The idea is not to print off summary tables,

statistics, and graphics for all variables as some kind of mandatory, although unwelcome task. Instead, the goal is to explore the data in a revealing and insightful way. This demands fast and flexible software, something that is not always available. Large statistical packages tend to be like oil tankers, hugely powerful and difficult to maneuver. The importance for EDA of how tables and graphics are presented and organized should not be underestimated. Analysts need displays that can be quickly assimilated and, if appropriate, immediately investigated in more detail. Being able to discard displays that are currently irrelevant is also valuable. Nothing inhibits clear thinking more effectively than cluttered screens on which you cannot see the wood for the trees (or should that be “on which you cannot see the content for the windows?”). It is quite possible that the need for statisticians to work with the powerful, large packages that are available to carry out standard analyses has discouraged the use of EDA.

In recent years, there have been substantial advances in data mining. It is important to note that data mining is not the same as EDA. EDA can be used to analyze any data set, whereas data mining is used for investigating datasets with many variables, which have probably been collected for purposes other than the current analysis. Data mining applies semi automatic methods to try to uncover information before involving the user. EDA should be carried out with direct user involvement to incorporate domain knowledge. For large data sets with few variables, EDA can generally be performed in the usual way. For large datasets with many variables, some initial screening analyses using the data-mining approach may be very helpful, though user knowledge of what is likely relevant and important may be more helpful still. EDA is concerned with the meaning and interpretation of data, that is, more with understanding than with prediction, to use Breiman's distinction (Breiman, 2001).

Why EDA?

There are many different reasons for carrying out EDA. An obvious initial step in any project is to discover what kind of data you are dealing with. What sort of variables are there? Are the data of high quality or are there erroneous values, missing values, or outliers? Are the data symmetric, skew, or clustered? Are there gaps in the data? Data quality is a particularly important issue and very difficult to handle

with formal methods. Every flawed dataset is flawed in its own way, and EDA is necessary to identify any weaknesses and to assess their impact.

EDA is often associated with initial data analyses, because it is easy to see how much it can help there. In fact, EDA can contribute at all stages of a project. It is useful for checking assumptions and for evaluating models (Gelman, 2004, makes the case strongly for incorporating exploratory graphical checks into the modeling process). It often complements more formal methods (for instance, using interactive mosaic plots to explain the results of log linear modeling of multivariate categorical data). It can be helpful in presenting results to others, showing how the properties of the data are reflected in models and vice versa.

EDA in Education

Quantitative research requires statistical modeling and statistical modeling requires EDA. There are studies on student performance (particularly international comparative studies like the Programme for International Student Assessment (PISA)). There are investigations of the effects of social background and school type. Some educational studies are observational (e.g., the school league tables that are produced in England and elsewhere) and EDA is important for assessing the characteristics of the populations studied and for qualifying how far any results can be generalized. Some studies are experimental, with groups carefully selected for the purposes of comparison. Here too, EDA makes a contribution, in monitoring how well the groups are matched.

EDA Methodology

Given data and a general goal of what the purpose of the analysis is, the first stage is to examine the variables individually, guided by domain experts. Tables, graphics, and basic statistics are all likely to be informative, but it is not sensible to simply draw and print out all possible displays! EDA should be discerning and sensitive, not unresponsive and inflexible. Results of initial EDA analyses will often identify various data-cleaning requirements and the need for further details on particular variables or cases. As always, this involves close cooperation with those who designed the study and collected the data. It may also become apparent that additional data will have to be collected.

Building on the knowledge acquired, one can continue with bivariate analyses, looking for associations between pairs of variables. At this point, data analysis and modeling start to overlap and various simple models may be built to gain understanding. When EDA was first discussed by Tukey, graphs had to be drawn by hand, and even

simple models could only be calculated with difficulty. Nowadays, large numbers of graphics can be drawn quickly and easily, and even complicated models can be fitted to data instantly. Statistical practice is only gradually catching up with the computing power that is already available. What is missing is not so much raw calculating capability as the tools to organize and integrate the resulting mass or mess of results.

Classical modeling is not the only approach for investigating the structure of data sets; there are many multivariate methods that may be applied, such as principal component analysis, multidimensional scaling, correspondence analysis, or cluster analysis. These methods have two features in common: they involve some kind of data reduction and they have little solid statistical grounding. The lack of statistical grounding makes them seem like exploratory techniques, for there are then no fully objective criteria as to which results to accept. However, it is worth emphasizing that the data-reduction aspect of these methods is not always in keeping with the spirit of EDA, because the combinations of variables (e.g., principal components) or of cases (e.g., clusters) may not be easy to interpret.

In general, there are no formal restrictions on which techniques may be used in EDA. Just as it can be sensible to draw a bar chart of continuous data (e.g., to identify frequently occurring values), it can be helpful to use methods that are not strictly valid (e.g., *t*-tests for non-normal data). The aim of EDA is to uncover information in data. Any information brought to light must be tested and properly qualified before being passed on, but the process of discovery should not be hampered by overly restrictive regulations. Any statistical model or technique can be employed in an exploratory way. Just because a data set has not been collected as a random sample from a specified population does not mean tests cannot be carried out as if the data has been collected that way. However, any results obtained have to be treated with caution and used only as approximate guidelines with accompanying qualifications.

The informal blending of a broad range of methods is a distinctive feature of EDA. Another is the extensive use of interactive analyses and graphics. Interaction encourages the incorporation of background information and the ability to respond to results obtained to guide further analyses in the most promising directions.

Techniques for EDA

Although methodology is at the heart of EDA, there are a few techniques which are particularly associated with it. Tukey proposed some graphical tools in connection with EDA and they have remained so in people's minds — sometimes regrettably long after their usefulness has

expired. Stem and leaf plots were a neat idea in the days of pencil and paper, but would rarely be the graphic of choice today, when computers are available to everyone. Box plots, however, have proved very informative and are an efficient way of comparing several distributions in parallel. It is essential to remark that, despite Tukey's original clear definition of a box plot, many alternative definitions are in circulation. You always have to check what definition has been used to ensure that you interpret box plots properly. Given a choice, Tukey's box plot is the one to be recommended. The hinges are drawn at the medians of the upper and lower halves of the data. The inner fences are drawn to the furthest points from the hinges inside $1.5 \times (\text{difference between the hinges})$. Individual points outside the inner fences are marked with circles, and extreme outliers, that is, points outside $3 \times (\text{difference between the hinges})$, are drawn as asterisks. **Figure 1** shows an example of employment data from the 299 German election constituencies in 2005. The skewness of the distribution is unsurprising (though it is perhaps surprising at first sight, that there are no constituencies with a zero value).

Transformations are often mentioned in connection with EDA and Tukey considered them a fundamental component. They are useful for working with skewed data and in other situations, but they suffer from the disadvantage that they may not be easy to interpret on the original scale. If all possible transformations are allowed, then some kind

Figure 1 A Tukey box plot of employment rates in agriculture, forestry, and fisheries in the German election constituencies in 2005.

of association among variables will often emerge. Transformations should be made use of judiciously.

Descriptive statistics play a basic role in EDA, though they can be overrated. Calculating correlation coefficients of all possible pairs of variables has a good chance of producing some surprising (and perhaps entertaining) relationships. The reported positive association between risk of obesity and the numbers declaring their religion as Jedi in the 2001 UK census is only one of many examples.

Graphics are essential in EDA. Analytic methods are good for assessing prespecified characteristics (e.g., could these data have come from a normal distribution?), but will not provide any clarification (e.g., because the empirical distribution is skew, there are many outliers, the values are clumped). Graphical displays can often indicate the presence of informative or curious features, which deserve further attention. Birthday distributions in Germany commonly show a sharp peak for the 1st of January. Apparently, immigrants sometimes arrive with no documented day of birth, but just the year. In these cases, they are assigned a birthday of the 1st of January. Another initially surprising feature of birthday distributions can be found among young footballers and other sportsmen: most of them have birthdays early in the year and there is a steady decline from January to December. The explanation is that only players born in a particular year can play in a team and so the ones born earlier in the year are older and therefore bigger and stronger. You do not find features like this without drawing appropriate graphics. Missing value plots, such as shown in **Figure 2**, are elementary tools that can reveal much about raw data. Although missing

Figure 2 A missing value plot for the exam marks of 126 children taking a maximum of nine school subjects. The children missing a mark in French have been selected and highlighted.

values arise in real data sets quite often, they are rarely to be found in textbook examples. Perhaps this is why they are not used more often. (An example is shown in **Figure 2**.)

Static graphics are very helpful for presenting results (once you know what results you want to present), while interactive graphics are more effective for EDA. To get the most value from multivariate graphic displays, especially parallel coordinate plots for continuous data and mosaic plots for categorical data, they have to be interactive. The abilities to query graphics (what are those outlying cases?), to link them (which are the female students' marks?), to reformat them (sort departments by graduate admission rates), to zoom in and out, to color cases by group, and so on, all support successful analyses. More sophisticated interactive tools such as extended querying, alpha-blending, and selection sequences (Unwin *et al.*, 2006) are also valuable and more developments can be expected.

Graphics alone are not enough and it is important to scrutinize any features found graphically with more formal statistical tools. Graphical displays and statistical models are gradually becoming more integrated in software, which will promote more authoritative applications of EDA in practice.

EDA Literature

In most scientific fields, there is a plethora of books and articles on any subject. EDA is an exception, because it is not specific techniques or models that are most important, but it is the approach. There are similarities with the literature on scientific method. While philosophers have written extensively and theoretically, there are very few books on the practice of science itself. Beveridge's excellent *The Art of Scientific Investigation* (Beveridge, 1950) is a rare example.

There is one classic book on EDA, which was written by John Tukey (Tukey, 1977). This was the culmination of many years work by Tukey in trying to convince other statisticians that data analysis was important. This campaign began with his famous 1962 article in the *Annals of Statistics* (Tukey, 1962). Tukey was a major figure, who contributed many central ideas, and had a major influence on the direction of statistics. Interestingly, his book was written just a little too early. The approach he described had then to be carried out by hand. The first personal computers were only just appearing on the scene. Within a few years they had transformed how data analyses could be carried out. Calculations, which had formerly involved tedious work, could be performed instantaneously and excellent graphics could be drawn without meticulous preparation by hand. Interactive graphics also became possible. They were first illustrated in the picturing, rotation, isolation, and masking (PRIM)-9 system for viewing three-dimension

(3D) rotating plots, the subject of a famous instruction film by Tukey and his collaborators. The only trouble with PRIM-9 (and indeed to a lesser extent with some of the systems that followed) was the enormous cost: one story mentions US\$10 000 an hour in the mid-1970s!

Many statistics textbooks refer briefly to EDA without discussing it in detail. This is a pity, though understandable. It is easier to write about techniques than about methodology (at least in mathematically oriented subjects). Discussions of EDA are more likely to be found in graphically oriented books such as (Unwin *et al.*, 2006), (Cook *et al.*, 2007), and (Theus *et al.*, 2008).

Example

As an example, consider the exam marks of 126 Irish schoolchildren in nine different subjects. The marks in each subject are out of 100. **Figure 2** shows a missing value plot (Unwin *et al.*, 1996). There is a bar for each variable, split into two sections. Each case is represented once in each bar. The proportion of cases with values is marked in gray to the left and the proportion of missings is in white to the right. The white section of the bar for German shows that few children had a mark in that subject. Not surprisingly (this is a real data set), no variable had a complete set of values.

To investigate a potentially interesting subgroup, the children missing a mark in French have been selected by clicking on the white section of the bar for French. These cases are highlighted in all bars and show up darker in **Figure 2**. The two sections of each bar are highlighted separately, for non-missings on the left and for missings on the right. At most there are then four sections in each bar. For instance, the bar for Irish shows from left to right: the proportion with marks in Irish but not in French; the proportion with marks in both; the proportion with marks in French but not in Irish; and the proportion with marks in neither. Almost all those missing a mark in French have a mark in German, which suggests that there must have been a choice between French and German for the children. Close examination of **Figure 2** shows that one child apparently had marks in both subjects and two had marks in neither (these features can more easily be seen by toggling the highlighting or by querying the bars in the plot).

The distributions of individual marks are also revealing. Parallel box plots of the marks in the nine subjects are shown in **Figure 3**. Common scaling has been used and the subjects sorted by the median mark. A number of curious features can be seen. In some subjects, there is a much bigger range than others, with teachers being prepared to give very low or very high marks. In English, all marks were between 27 and 79, while in French the range was

Figure 3 Parallel box plots of the exam results. All box plots are drawn to a common scale and they have been ordered by the median mark.

from 10 to 94. French had the highest median mark but the lowest individual mark.

To get more detail on the individual distributions, histograms may be drawn. Interactively adjusting the binwidth of the histogram for math marks suggests there might be a gap in the data just under the value 40. In **Figure 4**, the binwidths have all been set at exactly 2 with an anchor point of 0. There are gaps in math and history, but not in Irish or science. In the exam system in Ireland, 40 would usually be the pass mark and so a gap would not be surprising: some teachers may raise marks to 40 (a pass) or lower them to 37 (a clear fail) to avoid any discussion of marks with anyone getting 38 or 39. Others may not.

EDA Software

The main requirements for EDA software are a broad range of statistical tools, attractive graphics, and a multi-windows interface. No current package offers all of these capabilities though most provide some of everything and are continually improving in all categories. Interactive capabilities are the weak point of most of the larger packages, as it is difficult to combine many different models into one framework. The R language, originally an imitation of the S language developed for teaching, has gone from strength to strength and is, at the time of writing, the dominant software in statistical research. It can be used for EDA, but is by no means ideal. The same could be said of all the popular packages.

Several impressive researchers were attracted by the idea of interactive graphics early on and some excellent

pieces of commercial software appeared in the 1980s: MacSpin by the Donohoes, which implemented the ideas of PRIM-9, with a much better interface, for the Macintosh; Data Desk by Paul Velleman, which concentrated on providing a consistent implementation of interaction across all graphics types; JMP by John Sall, which was less strong in interactive graphics, but offered much more modeling power. Of these, MacSpin is long gone, partly because it really only provided rotating plots, while JMP and Data Desk are still available in substantially more advanced versions.

There have also been several interesting research software projects providing interactive tools. Peter Huber developed Interactive Statistical Programming (ISP) for interactive statistical analyses in general, but with less emphasis on graphics (Fleischer *et al.*, 1992). Xgobi and its successor Ggobi have extended the idea of rotating plots by incorporating projection pursuit criteria. In recent years, the Gobi group (Cook *et al.*, 2007) have broadened their approach to provide a wider range of graphics tools within their package. The Augsburg group has produced a number of software packages specifically for interactive graphics, including Heike Hofmann's MANET (Unwin *et al.*, 1996) (which introduced interactive mosaic plots and weighted plots) and Martin Theus's Mondrian (Theus, 2002) (which implemented fully interactive parallel coordinate plots and integrated statistical tools from R into graphical displays).

There exist many other packages that offer varying degrees of interactivity for a varying range of graphics, some more effective, some less effective. There are apparently differing views about how interactive should interactive software be to deserve the name.

Figure 4 Histograms of exam marks for four subjects. All graphics are on scales of 0–100 with anchor points of 0 and 100. The gaps just under 40 in math and history are clearly visible.

Future Developments in EDA

Increasing computing power and more flexible user interfaces will add to EDA's potential and increase its use. It will be more frequently employed at all stages of a data analysis and not just in the initial stages. Closer integration of statistical modeling capabilities will blur the line between classical statistical analysis and EDA. This reflects what actually happens in practice, as distinct from what is described in theory.

Factor Analysis: An Overview and Some Contemporary Advances

F A N Alhija, Tel Aviv University, Tel Aviv, Israel

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Common factor – It is a factor on which at least three observed variables substantially load.

Common factor analysis – It is a statistical technique which uses the correlation matrix between observed variables with communalities on the diagonal to estimate common factors and the loadings of the observed variables on the estimated factors.

Communality – It is the proportion of variance in the observed variable that is explained by a factor structure.

Confirmatory factor analysis – It is a factor analysis conducted for the aim of confirming a hypothesized factor structure.

Eigenvalue – It is the amount of variance in a set of observed variables explained by a common factor or component.

Exploratory factor analysis – It is a factor analysis used to explore the structure underlying a set of observed variables, usually, when there are no *a priori* hypotheses about the factor structure.

Factor analysis – It is a statistical technique used to reduce the dimensionality of a large number of observed variables to a fewer number of factors or components.

Factor rotation – It is a transformation of the principal factors or components in order to approach simple structure.

Loading – It is the correlation between a variable and a factor.

Model identification – An identified model is a model where a specific parameter value uniquely identifies the model, and no other equivalent formulation can be given by a different parameter value.

Model specification – It refers to the delineation of the causal relationships between variables that are thought to be possible (free to be estimated) and those relationships between variables that already have an estimated relationship, which can be gathered from previous studies (fixed).

Multilevel confirmatory factor analysis – It is a confirmatory factor analysis for testing measurement models in which the underlying attribute may vary as a function of levels of observations.

Multilevel data – It is hierarchically structured data whereby individuals are nested within groups. The number of levels can be two or more. Example: students within classes and classes within schools (three-level data).

Simple structure – The factor solution has a simple structure when each observed variable has substantial loading on one factor and each factor is defined by a set of observed variables that load substantially on it and have minor or zero loadings on the other factors.

Overview of Factor Analysis Methods

The term factor analysis refers to a family of statistical procedures used to either identify or validate some hypothesized structure among items/variables that tap a latent construct (Nunnally and Bernstein, 1994). There are two basic types of factor analysis: exploratory factor analysis (EFA) and confirmatory factor analysis (CFA).

Exploratory Factor Analysis

Typically, EFA is used to explore the underlying dimensions of a construct. The primary considerations inherent in the use of factor analysis include conceptual/theoretical considerations, design considerations, statistical considerations, and reporting considerations.

Conceptual/theoretical considerations

Factor analysts should choose an appropriate factor model, usually component analysis (CA) versus EFA, in accordance with the purpose of the analysis. If the purpose of factor analysis is essentially data reduction, then CA will yield a fewer number of components which represent the original set of variables. The resulting component scores are used in follow-up analyses.

If the goal of the researcher is to interpret the correlations among variables as arising from a smaller set of latent variables/factors, EFA is the method of choice. The latter model recognizes that variables are measured with error and yield coefficients which are less biased.

Design considerations

First, the theoretical and empirical aspects of the construct under inquiry must be thoroughly considered. Second, a sufficient number of items or test questions must be written or obtained to adequately measure the dimension(s) supported by the theory. Factor analysts have suggested a minimum of three to five items per factor. However, the breadth of the construct or its dimension definitions and the expected number of dimensions should be taken into account before deciding on the number of items to include. Third, sufficient sample size is necessary to stabilize estimates and to separate common variance from unique variance. The more exploratory the analysis, the larger the sample needs to be. A rule of thumb is that five to ten subjects per variable are required for a proper factor analysis. However, the number of variables/items, the potential number of factors, the variable to factors (v/f) ratio, the magnitude of factor loadings, and the size of the interfactor correlations need to be considered before an estimate of sample size can be suggested.

Other issues such as restriction in range, linear dependencies in the data, and variables that are not interval should be appropriately taken care of. The more restricted the range of the scores in the observed data, the more problematic the analysis will be. Restriction of range attenuates the intervariable correlations downward which in turn affects the magnitude of loadings, the amount of variance explained by each factor, and the ability to extract the correct number of factors.

Linear dependencies can easily occur when one is factor analyzing a large number of variables (say $v > 30$), due to the increased likelihood that two or more variables may be highly correlated. Linear dependency can result in a zero matrix determinant and an ill-conditioned matrix that cannot be inverted and therefore should be resolved prior to conducting the factor analysis.

The nature of the variables used in factor analysis is often an overlooked issue. Whether the variables are measured on a continuous, ordinal, or dichotomous scale should be treated appropriately. As the number of response categories is reduced, the likelihood increases that the Pearson correlation coefficients will be distorted and more relevant matrices of association should be used as an input.

Statistical considerations

Decisions regarding extraction method, number of factors, and the type of rotation should be made. The most commonly used extraction method within CA is principal component analysis (PCA) while principal axis factoring (PAF) is the commonly used extraction method with EFA. Components or factors are extracted from either the full correlation matrix (with unities on the main diagonal) or the reduced correlation matrix (with communalities – the proportion of each variable's variance explained by a factor

structure – on the main diagonal) one at a time, such that each factor extracts maximum variance from the variables and is independent of the previously extracted factors.

Numerous procedures for determining the number of factors exist. However, the most commonly used are the Cattell's scree plot and Kaiser's eigenvalue greater than one criterion, maybe because these are the default in major computer programs. Researchers are advised to consult several criteria when determining the number of factors. For a more comprehensive overview, see Benson and Nasser (1998).

Through rotation, a transformation of the principal factors or components in order to approach simple structure, the variance extracted is redistributed more evenly across the factors making factor interpretation easier. Two forms of rotation are applicable: orthogonal or oblique. Orthogonal rotation restricts the factors to be independent of one another; whereas oblique rotation allows the factors to be correlated.

The principle applied by most factor analysts to guide factor rotation is simple structure. That is for every pair of factors, there should be several variables whose loadings are high on one factor and low or near zero on the other factor. A loading of at least 0.30 is suggested to define a factor.

Varimax is the most commonly used option for orthogonal rotation. Another popular orthogonal rotation method is quartimax (Thompson, 2004). With orthogonal rotation, three matrices are provided: the unrotated factor matrix, the rotated factor matrix, and the transformation matrix. Usually, only the rotated factor matrix is interpreted.

The most frequently used oblique rotation method is direct oblimin (Benson and Nasser, 1998). Other popular methods for oblique rotation are promax and quartimin. With oblique rotation, four matrices are produced: the unrotated factor matrix, the factor pattern matrix, the factor structure matrix, and the factor correlation matrix. Typically, the factor pattern matrix and the factor correlation matrix are interpreted. A summary and comparison of many of the orthogonal and oblique rotation methods are provided in Gorsuch (1983).

Reporting consideration

Researchers should present sufficient theoretical background for readers to follow the decisions made regarding: the choice and the number of variables, sample size, factor model, input matrix, factor extraction, and factor rotation. The nature of EFA makes it typical to consider several models and rotated solutions in the process of arriving at the final model(s). The models considered could be derived from the literature which may suggest different numbers of factors or relations between factors. The analysis should be rerun after eliminating malfunctioning items. In such cases, eliminating items can result in a sharpening of the factor pattern/structure.

Confirmatory Factor Analysis

The technique of CFA analyzes *a priori* measurement models in which both the number of factors and their correspondence to the indicators are explicitly specified. CFA is then used to assess the fit of a hypothesized factor structure to the data.

Both EFA and CFA are part of the generalized linear model (GLM) and therefore, many of the concepts discussed with regard to EFA apply to CFA as well; however, the two methods differ with regard to several aspects which are summarized in **Table 1**.

Many decisions are inherent in the use of CFA. Some are made prior to the analysis and others are made following the analysis.

Pre-analysis decisions

Rival models

CFA involves testing the fit of models to the data. Other rival models should be tested in order to support the disconfirmability of the model. Disconfirmable and/or plausible models for CFA models are context specific, and some such models are either theoretically or empirically driven.

Table 1 Summary of the primary differences between EFA and CFA

EFA	CFA
The factor model is determined by the analysis	The factor model must be specified <i>a priori</i>
Rotation is performed to reach simple structure	Rotation is irrelevant because the <i>a priori</i> models typically specify simple structure
All parameters should be estimated	The researcher can fix certain parameters to mathematically permissible values, while freeing other model parameters to be estimated
Certain factor loadings may be expected, but cannot be incorporated into the analysis	One or more specific models, each containing some fixed and some freed parameters must be declared as input into the analysis
Error variances cannot be correlated	Error variances are allowed to correlate
Either all pairs of factors are assumed to be correlated or all factors are orthogonal	All pairs of factors can be correlated or only part of them can be correlated
Loading or inter-factor correlation equality constraints cannot be imposed	Equality constraints can be imposed on factor loadings, variances, and inter-factor correlations
Can be performed with SPSS, SAS, BMSBP, STATISTICA, and other statistical programs	Can be performed with LISREL, AMOS, CALIS, and MPLUS

Model identification

A model is said to be identified when, for a given research problem and data set, sufficient constraints are imposed such that a single set of parameter estimates is yielded by the analysis. A necessary, but not sufficient condition, for model identification is that the number of parameters being estimated should not be greater than the available degrees of freedom. The number of degrees of freedom in CFA equals the difference between the number of unique entries in the covariance matrix ($v(v+1)/2$), which is a function of the number of observed variables (v) in the analysis and the number of parameters (p) to be estimated ($df = v(v+1)/2 - p$). Model identification also requires that the measurement scale of each latent variable is specified or constrained in order to set the metric for the estimate.

CFA models can be identified by fixing one of the factor loadings to any number, usually 1. This indicates that the scales of the scores on the latent variable are some multiple of the selected observed variables. Alternatively, the factor variances can be constrained to be any mathematically positive number, usually 1.

Matrix of association to be analyzed

The default choice in most CFA programs is the covariance matrix. The computation of both the Pearson correlation matrix and the covariance matrix assumes data scaled in intervals. In CFA, for statistical reasons, it is preferable to analyze the covariance matrix which yields correct results as long as the data are appropriately scaled and distributed. Whenever there is some doubt regarding either the scaling of the data, or the selection of the input matrix of association, it is advisable practice to apply several reasonable choices such as using polyserial, tetra-choric, or polychoric correlations matrices as input with weighted least squares as an estimation method.

Multivariate normality

Some statistical estimation theories (e.g., maximum likelihood) assume multivariate normality, particularly regarding standard errors of model parameter estimates and some CFA model fit statistics. Two primary ways can be used to test the multivariate normality of the data. First, the graphical technique described by Thompson (1990) can be used with at least 25 observed variables. Second, a statistical test of the multivariate coefficient of kurtosis is available in CFA/SEM software.

If the assumption of multivariate normality is violated, one can use distribution-free parameter estimation theory (e.g., ADF). Nonetheless, this theory requires very large samples compared with the commonly used theories. An alternative is to use item parcels by bundling together observed variables in a way that reduces non-normality. However, this strategy is subject to the general limitations of parceling methods.

Parameter estimation theory

Two alternative parameter estimation theories are fairly commonly used in CFA. Maximum likelihood (ML) theory is the default theory in most statistical packages. ML requires that the data have at least an approximately multivariate normal distribution. Asymptotically distribution-free (ADF) estimation theory yields estimates that tend to be accurate regardless of the distribution shapes as the sample size becomes increasingly large.

Post-analysis decisions

Two major decisions should be made following the analysis: evaluation of model fit and consideration of specific errors in model specification.

Model fit statistics

Numerous indices of fit are provided in the literature and researchers are advised to consult several of them when evaluating model fit. Among the most commonly used are χ^2 goodness-of-fit statistics. A well-fitting model would be expected to have a non-significant χ^2 and a small χ^2/df ratio. Nonetheless, when the sample size is large, substantively correct models also yield significant values for χ^2 . Therefore other fit indices such as the comparative fit index (CFI), the standardized root mean square residual (SRMR), and the root mean square error of approximation (RMSEA) are commonly used. Recommendations for model fit cutoff criteria suggest that CFI should be at least .95, RMSEA < 0.08, SRMR < 0.06. A comprehensive discussion of goodness-of-fit indices is provided in Browne and Cudeck (1993).

Model misspecification statistics

Using irrelevant observed variables, omitting relevant observed variables, using wrong estimation theory, freeing parameters that should be fixed, or vice versa, are examples of model misspecifications. CFA programs do not tell researchers whether they used relevant observed variables but they yield diagnostics regarding the parameters that were freed but possibly should have been fixed and vice versa. In these cases researchers tend to re-specify the model and re-test the re-specified one. Model re-specification is reasonable when each change can be justified theoretically, and when the fit of the re-specified model can be evaluated in a holdout or independent sample.

Factor Analysis of Categorical Data

When developing test or questionnaire scales, the variables subjected to factor analysis are frequently not continuous. Rather, they are often dichotomous or polychotomous Likert scale items. The covariance matrix for these observed categorical variables will not fit the common

factor model, or factor analysis of observations on these variables will yield biased factor loadings. In these cases, besides the traditional parameter estimates, one must also estimate the so-called threshold parameters.

The methods that have been proposed for performing this estimation commonly obtain estimates of polychoric and polyserial correlations at one or more stages of computation. A theoretically appropriate method fits the CFA model to polychoric correlation using either weighted least squares (WLS) or robust WLS. This approach, however, assumes that a continuous, normal latent process determines each observed variable. This assumption cannot really be tested. Therefore some researchers suggest using composites of several items which are often called item parcels so that the resulting scores would be close enough to continuous variables.

Categorical data are likely non-normal; hence, the classic normal theory methods can give test statistics that are seriously biased. Therefore, the ADF approach is suggested as a possible solution. However, this free-distribution approach requires large samples. Another option is the use of rescaled statistics like the Satorra-Bentler scaled chi-square statistics.

Procedures for analyzing categorical variables are implemented in programs such LISCOMP LISTEL, PRELIS, and MPLUS.

Confirmatory Factor Analysis of Multilevel Data

When applied to hierarchical data, which often occurs in practice, CFA is frequently misused. Until recently, the conventional practice of assessing the factor structure of hierarchical data where individuals are nested within groups, such as students nested within classes or employees within organizations, involved either (1) performing the factor analysis at the individual level while ignoring the hierarchical structure of the data or (2) applying the factor analysis only to group-level data. Both approaches yield problematic results (Muthén, 1994) because a non-hierarchical model is inadequate.

In the first case, when the total sample covariance matrix (S_T) is factor analyzed, the assumption of independent and equally distributed observations that underlie factor analysis is violated with clustered observations that are likely to be related. Violation of this assumption biases parameter estimates, standard errors, and the power of statistical significance tests. This can result in either incorrect conclusions regarding the factor structure of the scale under investigation or the appropriateness of the items for measuring the latent construct.

In the second case, the sample between-group covariance matrix (S_B) will be a biased estimate of the population between-group covariance matrix (\sum_B) because it is a function of the population between-covariance matrix

(\sum_B) and the weighted group-size within-group covariance matrix (\sum_W) (Muthén, 1994).

The use of multilevel confirmatory factor analysis (MCFA) is also justified when constructing aggregate-level and multilevel theories are of interest. These theories typically include constructs that may function differently at aggregate levels of analysis (e.g., Heck and Thomas, 2000). Therefore, it is imperative to make sure that a scale measuring a group-level construct exhibits the desired construct validity properties at the aggregate level of analysis.

Currently, it is possible to assess the similarity of the factor-loading patterns across levels of analysis by reformulating the testing of separate covariance matrices across data levels as a test of covariance matrices across different groups. In the case of two levels, one model is formulated for the individual-level variation and another is formulated for the between-group variation in the parameters and the features of a within-group and between-group measurement model are tested simultaneously.

Muthén (1994) demonstrated that current multiple-group SEM software packages – such as LISREL, EQS, or AMOS – can be modified to handle multilevel factor analysis. One available software program that facilitates the specification and testing of two-level structured model is STREAMS that allows relatively easy specification of a variety of structural models. Muthén's Mplus software program specifies multilevel SEM models within which MCFA is executed and creates the necessary within- and between-group matrices in unbalanced designs. EQS version 6.1 features two different methods for performing multilevel SEM analyses.

The MCFA estimation process

Muthén (1994) proposed a five-step procedure to follow when conducting MCFA:

1. conventional CFA on the sample total covariance matrix (S_T);
2. establishment of between-group level variation;
3. confirmatory factor analysis of the sample-pooled covariance matrix (S_{PW});
4. confirmatory factor analysis of the sample between-group covariance matrix (S_B); and
5. multilevel confirmatory factor analysis (MCFA).

The first four steps produce basic information regarding the factor structure of the scale data at different levels of analysis along with information necessary to justify the multilevel analysis. The final step consists of the actual MCFA, and therefore provides the most direct evidence for confirming or refuting the hypothesized multilevel model. Each of the five steps is elaborated through an empirical illustration of the MCFA procedure.

An Illustrative Application of MCFA

Method

Data source and sample

Data used for this illustration were obtained from 3117 students enrolled in 272 courses at a major teacher training college in Israel. The sample size of students from each course varied from 6 to 64, with an average sample size of 16.14. Student ratings of one randomly selected course taught by each instructor constituted the data.

The instrument

Student ratings were collected using an evaluation questionnaire with 13 statements measuring teaching quality. Students responded to each item using a seven-point Likert-type scale designed to assess three dimensions of teaching quality: course content (five items), instructor–student relations (four items), and planning and teaching strategy (four items). Reliability coefficients (Cronbach's alpha) corresponding to the three factors were estimated to be 0.87, 0.86, and 0.84, respectively.

The hypothesized factor model

In earlier research, exploratory factor analysis of the data collected with the same questionnaire yielded three factors as described above (Fresko *et al.*, 2003). Since students are nested within courses, their ratings of college teaching are likely to be nonindependent. Therefore, a three-factor two-level model was formulated and the research hypothesis was that the model should fit the data at both levels (see Figure 1).

Analysis and Results

Preliminary analysis

The individual responses to the 13 items were screened to detect substantial skewness, kurtosis, and/or outliers. Values were acceptable for all 13 items. The total (S_T), the pooled within (S_{PW}), and the sample estimated between-group (S_B) covariance matrices were calculated.

Model estimation and assessment of fit

In this illustration, all the analyses were conducted using EQS version 6.1 with the MUML estimator that produces maximum likelihood parameter estimates, robust standard errors, and a mean-adjusted χ^2 goodness-of-fit statistics for equal group size. For unbalanced data, MUML is a robust limited-information estimator. No specific criteria for evaluating model fit have yet been offered for multilevel modeling. Researchers, therefore apply the same criteria used in the context of SEM as they do to MCFA modeling.

The five-step results are as follows:

Step 1: Conventional CFA on the S_T matrix. The parameter estimates and the fit statistics resulting from this analysis

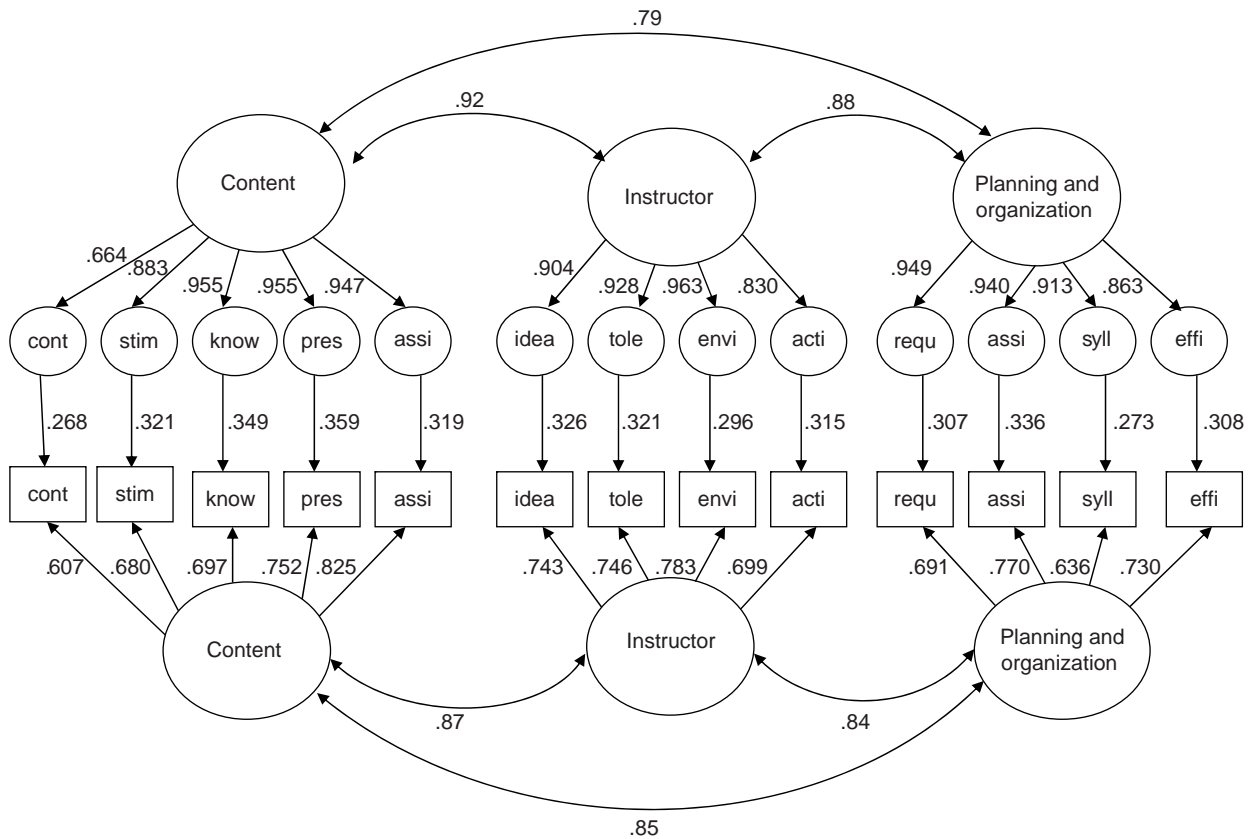

Figure 1 The sample three-factor multilevel model. assi = assignments' contribute to understanding, idea = encourage ideas exchange, tole = instructor is tolerant, envi = creates pleasant environment, acti = activate students, requ = clear requirements, assi = clear assignments, syll = follows the syllabus, effi = use class time efficiently. Errors can be calculated as: $e = (1 - \text{loadings}^2)^{1/2}$.

Table 2 Model fit for *a priori* one- and two-level models^a

Models	χ^2	df	CFI	RAMSEA (C.I.)	SRMR
Total	2046.47	62	.93	.101 (.098, .105)	.043
Within	1525.85	62	.93	.087 (.083, .91)	.042
Between	6907.30	62	.84	.197 (.193, .201)	.059
Multilevel (with all equality constraints)	1977.64	124	.94	.098 (.094, .102)	.049

^aAll χ^2 values are statistically significant ($p > .05$).

df – degrees of freedom; CFI – comparative fit index; RAMSEA – root mean square error of approximation; SRMR – standardized root mean square residual.

are biased when the degree of nonindependence is sizable, particularly when group size is large (Muthén, 1994) or when the factor structure at the within- and between-group levels differs.

The fit of the three-factor model was borderline with significant χ^2 [$\chi^2(62) = 2046.47$, $df = 62$, $p > .05$], and values of .93, .043, and .101 for CFI, SRMR, and RMSEA, respectively. Standardized loading for the 13 items ranged from .624 to .868, with all values statistically significant, suggesting that the items adequately represent the latent constructs.

Step 2: Establishing between-group (course) level variation. Application of MCFA to the data at hand is justified if the systematic between-group variation for each observed variable is relatively large, indicating the multilevel nature of the data. Several techniques have been designed to detect the multilevel character of the data including r_{wg} , η^2 , WABA, and the intra-class correlation (ICC) (James *et al.*, 1984; 1993; Dansereau *et al.*, 1984; Muthén, 1994; Kowzlowzki and Klein, 2000). Muthén's ICC was used in this illustration to quantify the proportion of the between-group variation relative to the total variation in the data.

^aLoading fixed to zero to set the metric

The values of ICC range from 0 to 1, with higher values indicating a greater proportion of between-group variance and potential bias if the multilevel nature of the data is ignored. The values for the 13 observed indicators ranged from .230 to .343 (**Table 2**). The ICC values indicated that the between-course variation is relatively sizable, justifying the conduct of an MCFA ($ICC \geq .05$ justifies multilevel analysis).

Step 3: CFA of the S_{PW} matrix. The S_{PW} based on individual-level scores and adjusted for respective group means is used for the analysis of the disaggregate factor structure.

For this illustration, S_{PW} was calculated using EQS version 6.1. The number of observations for the pooled within-group covariance matrix (N-G) was $3117 - 272 = 2845$, whereas for the course level it (G) was 272. The three-factor model based on S_{PW} produced a better fit to the data than the one based on S_T ($\chi^2 = 1525.852$, $df = 62$, $p < .001$, CFA = .93, SRMR = .042, and RMSEA = .088). This indicates that either the construct-relevant variance is substantial at the student level or that the factor structure for the course level differs from that of the student level.

Step 4: CFA of the S_B matrix. The structure obtained for the within-group level may not hold for between-group level data. The appropriateness of the between-group factor structure is therefore examined. Either an estimate of the population between-group covariance matrix or the sample between-group covariance matrix S_B adjusted for the weighted group-size within-group effect (Muthén, 1994) can be used.

The estimated between-group covariance matrix obtained by EQS version 6.1 was used here. The fit results (**Table 2**) reveal that the course level model shows considerably poorer fit to the data. In particular, the RMSEA (.197) and the CFI (.84) reflect poor fit. Alternative two-factor and one-factor models produced an even worse fit. Therefore, for the sake of illustration, it was decided to proceed with the multilevel step with the three-factor model at the student and the course levels.

Step 5: MCFA. The fit results pertaining to the MCFA with all equality constraints across the two levels indicated acceptable fit [$\chi^2 = 1977.640$, $df = 124$, $p < .001$, CFA = .94, SRMR = .049, and RMSEA = .098(.094, 102)]. **Table 2** summarizes the fit data for the conventional CFA model, the within- and between-course models and the two-level model. **Table 3** summarizes the estimated factor loading values and the standard errors for the 13 items in the total, student-level, course-level, and multilevel models together with their ICC values. **Figure 1** depicts the two-level factor model of the student ratings data along with the student-level and course-level factor loadings and inter-factor correlations. The factor loadings at the course-level were stronger than those at the student-level. While the factor loadings obtained from the student-level and the course-level separately were similar in value to the corresponding estimates obtained from the multilevel analysis, the standard errors of these estimates

were larger than those associated with the student and course-level models. This indicates that taking the multilevel structure of the data into account results in different standard errors from those obtained in the disaggregated and aggregated data models separately. Although the fit of the between-course model was poor when analyzed separately, simultaneous analysis of the two-level data produced a better fit.

Summary and Implications

Factor analysis is one of the most commonly used methods in educational and psychological research. Still, it is frequently misused and critical issues are overlooked. Researchers employing factor analysis should carefully review the theoretical and empirical literature in the substantive areas of interest, select a sufficient number of variables that are as representative as possible of the content domain, be aware of the metric used to measure variables, avoid including linearly dependent variables, select a sufficient sample size which is as representative or as random as possible, and use theory to guide the factor analytic decisions which need to be made in the analysis.

Categorical and hierarchical data require special attention and careful selection of appropriate procedures that take the special characteristics of these data into account and therefore yield more accurate factor model estimates. With categorical data, factor analysts should use the appropriate matrix of association as an input for the analysis (e.g., polychoric and polyserial correlation matrices), and consider distribution-free estimation theory or item parcels to avoid inaccuracies resulting from a violation of the normality assumption.

As illustrated in this article, MCFA allows the researcher to investigate the stability of a proposed factor model across organizations such as schools, colleges, universities, and hospitals. Through this approach, the researcher can develop a more refined analysis of construct validity and obtain more accurate estimates at the various levels of analysis. It is hoped that the MCFA framework will provide researchers with an analytic tool that is both powerful and easy to comprehend in order to facilitate addressing the inherent nature of the structure of the data at hand.

Glossary

Linear predictor – A linear combination of explanatory variables that is part of a regression model or generalized linear mixed model.

Link function – A function applied to the conditional expectation of the response variable before this is equated to the linear predictor (in a generalized linear model). Examples are the identity, log, and logit link functions.

Random coefficient – Cluster-specific coefficient of a covariate in a regression model for clustered data that varies randomly between clusters.

Random intercept – Cluster-specific intercept in a regression model for clustered data that varies randomly between clusters.

Logistic Random-Intercept Model

To introduce the idea of generalized linear mixed models, we consider the following example. The Program for International Student Assessment (PISA) is an international educational survey funded by the Organisation for Economic Co-operation and Development (OECD) that measures attainment in reading, mathematics, and science among 15-year-old students. Using the United States sample of PISA 2000, we estimate the relationship between reading proficiency (Prof_{ij}) of student i in school j and the following covariates:

- Fem_{ij} : indicator for student being female;
- SES_{ij} : international socioeconomic index (continuous), grand-mean centered and divided by 20;
- HS_{ij} : indicator for highest education level of either parent being high school graduate;
- Coll_{ij} : indicator for highest education level of either parent being college graduate; and
- Eng_{ij} : indicator for test language (English) spoken at home.

Prof_{ij} is a binary variable (1 = Yes, 0 = No); therefore, an appropriate level-1 model is a logistic regression model. Specifically, the log of the odds that the student is proficient versus not proficient is specified as a linear function of the covariates,

$$\log \left\{ \frac{P(\text{Prof}_{ij} = 1)}{P(\text{Prof}_{ij} = 0)} \right\} = \beta_{0j} + \beta_1 \text{Fem}_{ij} + \beta_2 \text{SES}_{ij} + \beta_3 \text{HS}_{ij} + \beta_4 \text{Coll}_{ij} + \beta_5 \text{Eng}_{ij}$$

(Here $P(\cdot)$ refers to the conditional probability, given β_{0j} and the covariates.) The school-specific intercept β_{0j} represents the log-odds of being proficient for students in school j when all the covariates take the value zero, that is for males with average socioeconomic status (SES) whose parents' highest education level is less than high school and who do not speak English at home. The regression coefficient of a covariate represents the increase in log-odds per unit increase in the corresponding covariate when the other covariates and β_{0j} remain constant. These coefficients are sometimes referred to as conditional or school-specific effects because β_{0j} is held constant. Exponentiating the coefficients yields school-specific odds ratios.

The level-2 model for school j is

$$\beta_{0j} = \gamma_{00} + \gamma_{01} \overline{\text{SES}}_j + \zeta_{0j}$$

where $\overline{\text{SES}}_j$ is the mean SES for school j , and ζ_{0j} is a school-specific random intercept assumed to be independent of the covariates and independent across schools with $\zeta_{0j} \sim N(0, \psi)$.

Substituting the school-level model into the student-level model and writing η_{ij} for the log-odds, we obtain the so-called reduced form

$$\eta_{ij} = \gamma_{00} + \gamma_{01} \overline{\text{SES}}_j + \beta_1 \text{Fem}_{ij} + \beta_2 \text{SES}_{ij} + \beta_3 \text{HS}_{ij} + \beta_4 \text{Coll}_{ij} + \beta_5 \text{Eng}_{ij} + \zeta_{0j}$$

a logistic regression model with both student-level (or level 1) and school-level (or level 2) covariates and both a fixed intercept γ_{00} and a random intercept ζ_{0j} .

Maximum likelihood estimates for the logistic random intercept model are presented in **Table 1**. Higher school mean SES, being female, higher individual SES, having at least one parent with a college education, and speaking English at home are all associated with a significantly greater odds of reading proficiency at the 5% level. For an indicator variable, the odds ratio represents the ratio of the odds for two groups, holding constant the other covariates. For instance, the estimated odds ratio of 1.9 for Eng_{ij} means that students who speak English at home have 1.9 times the odds of being proficient in comparison to students who do not speak English at home for a given

school mean SES, gender, parents' education, and random intercept ζ_{0j} .

For a continuous covariate, the odds ratio can be interpreted as the effect of increasing the covariate by a unit; therefore, it is important to understand the scale of the covariate. Individual SES has a standard deviation of 0.88 and school mean SES has a standard deviation of 0.45. Each unit increase in school mean SES is associated with a quadrupling in the estimated odds of being proficient, controlling for individual SES, the other covariates, and the random intercept. Such an additional effect of the school mean of a variable after controlling for the individual-level variable is sometimes referred to as a contextual effect. Here it could be due to the effect of the peers' SES, as well as any omitted variables that are correlated with school SES, such as school resources, parent involvement, and teacher qualifications.

If we had omitted school mean SES from the model, the estimated coefficient of individual SES would have been greater (0.41) due to absorbing some of the contextual effect. Using econometric terminology, we would have had an endogeneity problem because the random intercept, representing the combined effects of all omitted covariates at the cluster level (including school mean SES), would be correlated with individual SES. Another way of thinking about the problem is by remembering that the random intercept is assumed to be uncorrelated with the covariates; therefore, the effects of included covariates are not controlled for any possible school-level confounders. Such control can be achieved for an individual level-1 covariate by mean centering it and/or including its cluster mean as an additional covariate. Alternatively, we can eliminate cluster-level confounding for all level-1 covariates by specifying fixed effects for schools. In linear models, this could be accomplished by including indicator variables for schools. In logistic regression models, an appropriate approach is conditional maximum likelihood estimation. Using this method gives similar estimated coefficients except for a lower estimate of 0.46 for Eng_{ij} , suggesting that there might be an endogeneity problem or contextual effect for this variable.

It is useful to visualize the magnitude of the effects of some variables on the probability of reading proficiency,

Table 1 Maximum likelihood estimates for logistic random intercept model

Parameter	Est	(SE)	OR	(95% CI)
γ_{00}	-2.02	(0.29)		
$\gamma_{01}[\text{SES}_j]$	1.38	(0.18)	4.0	(2.8,5.7)
$\beta_1[\text{Fem}_{ij}]$	0.56	(0.10)	1.7	(1.4,2.1)
$\beta_2[\text{SES}_{ij}]$	0.29	(0.07)	1.3	(1.2,1.5)
$\beta_3[\text{HS}_{ij}]$	0.39	(0.25)	1.5	(0.9,2.4)
$\beta_4[\text{Coll}_{ij}]$	0.71	(0.23)	2.0	(1.2,3.3)
$\beta_5[\text{Eng}_{ij}]$	0.62	(0.29)	1.9	(1.2,2.9)
ψ	0.27	(0.09)		

holding other variables constant. For instance, we can consider boys whose parents' highest level of education is high school and who have SES equal to the overall mean, and obtain predicted probabilities as a function of school mean SES and the indicator variable for speaking English at home. A graph of these predicted probabilities (for the range of school mean SES in the data) is shown in **Figure 1**, where the dashed curves are for students who speak English at home and the solid curves are for students who do not speak English at home. For each line pattern, the curve that is closer to 0.5 represents the population averaged or marginal probability, after integrating or averaging out the random intercept, whereas the other curve represents the conditional or school-specific probability, with the random intercept set to 0, which is also the median probability.

We can see that school mean SES has a large effect, with predicted probabilities differing by more than 0.4 between the lowest and highest SES schools. Speaking English at home increases the probability by about 0.1 for average and above average SES schools. In the very low SES schools, boys with average SES, but whose parents' highest level of education is high school, have very low probabilities of reading proficiency.

Random Coefficient Models

The random intercept model for the log-odds considered in the previous section had the form

$$\eta_{ij} = \beta_{0j} + \beta_1 x_{1ij} + \cdots + \beta_p x_{pij}$$

Figure 1 Predicted probability of reading proficiency as a function of school mean SES for students who do (dashed curves) and do not (solid curves) speak English at home (with $\text{Fem}_{ij} = 0$, $\text{SES}_{ij} = 0$, $\text{HS}_{ij} = 1$, and $\text{Coll}_{ij} = 0$). For each line pattern, the curves closer to 0.5 are marginal probabilities and the other curves, median probabilities. Reproduced by permission of the publisher from Rabe-Hesketh, S. and Skrondal, A. (2008). *Multilevel and Longitudinal Modeling Using Stata*, 2nd edn, Figure 6.3. College Station, TX: Stata Press. Copyright 2008 by StataCorp LP.

where β_{0j} is a school-specific random intercept and x_{pij} ($p = 1, \dots, P$) are level-1 covariates with fixed regression coefficients β_p .

In random coefficient models, not only is the intercept school specific, but the effects of at least some level-1 covariates also vary between schools. The simplest example is a model with a random intercept and a random slope for a covariate x_{1ij} . The level-1 model for the log-odds then has the form

$$\eta_{ij} = \beta_{0j} + \beta_{1j}x_{1ij} + \beta_2x_{2ij} + \dots + \beta_px_{pij}$$

where x_{1ij} has a school-specific regression coefficient or slope β_{1j} , whereas the other level-1 covariates have fixed regression coefficients β_2, \dots, β_p .

The school-specific intercept and slope each have their own level-2 model of the form

$$\begin{aligned}\beta_{0j} &= \gamma_{00} + \gamma_{01}w_{1j} + \dots + \gamma_{0Q}w_{Qj} + \zeta_{0j} \\ \beta_{1j} &= \gamma_{10} + \gamma_{11}w_{1j} + \dots + \gamma_{1Q}w_{Qj} + \zeta_{1j}\end{aligned}$$

where w_{1j}, \dots, w_{Qj} are school-level covariates. The school-specific random intercept ζ_{0j} and random slope ζ_{1j} are typically assumed to have a bivariate normal distribution with zero as mean for given covariate values.

Substituting the level-2 models into the level-1 model produces a reduced form with cross-level interaction terms. For instance, the model for β_{1j} includes the term $\gamma_{11}w_{1j}$, and, since β_{1j} multiplies x_{1ij} , we obtain the cross-level interaction $\gamma_{11}w_{1j}x_{1ij}$. Random coefficient models could, of course, also include random effects of more than one covariate varying at level-1.

Different Response Types

All generalized linear mixed models have a so-called linear predictor η_{ij} of the form shown in the previous section. The relationship between the linear predictor and the observed response y_{ij} can be specified in a number of different ways depending on the type of response variable. First, a conditional distribution for y_{ij} is specified as a function of the conditional expectation μ_{ij} , given the covariates and random effects. Second, a link function $g(\cdot)$ is specified so that

$$g(\mu_{ij}) = \eta_{ij}$$

The conditional response distribution is from the exponential family and is characterized by the conditional expectation μ_{ij} as well as a dispersion parameter ϕ that affects the conditional variance

$$\text{Var}(y_{ij}|\mu_{ij}) = \phi V(\mu_{ij})$$

where the variance function $V(\mu_{ij})$ is determined by the chosen distribution.

We briefly discuss the most common generalized linear mixed models for continuous responses, binary responses, and counts.

Continuous Responses

In the continuous case, a linear mixed model is typically assumed, in which the conditional response distribution is normal,

$$y_{ij}|\mu_{ij} \sim N(\mu_{ij}, \sigma_e^2)$$

and the link function is the identity link

$$\mu_{ij} = \eta_{ij}$$

The variance function is $V(\mu_{ij}) = 1$ and the dispersion parameter is $\phi = \sigma^2$.

Binary Responses

Binary responses are assumed to be independently Bernoulli distributed as

$$y_{ij}|\mu_{ij} \sim \text{Bernoulli}(\mu_{ij})$$

for given μ_{ij} . Here the conditional expectation μ_{ij} is also the conditional probability $P(y_{ij} = 1)$ for given values of the covariates and random effects. The most common link function is the logit link

$$\eta_{ij} = \text{logit}(\mu_{ij}) \equiv \log\left\{\frac{\mu_{ij}}{1 - \mu_{ij}}\right\} = \log\left\{\frac{P(y_{ij} = 1)}{P(y_{ij} = 0)}\right\}$$

which can be interpreted as the log of the odds that y_{ij} is 1. An alternative link function is the probit link $\Phi^{-1}(\mu_{ij})$, the inverse standard normal cumulative distribution function. The variance function in either case is

$$V(\mu_{ij}) = \mu_{ij}(1 - \mu_{ij})$$

and the dispersion parameter is equal to 1.

If there are several ($n_{ij} > 1$) independent binary responses per unit ij , the conditional distribution of the number of responses that are 1 is binomial with probability of success μ_{ij} and number of trials n_{ij} . In this case, the variance function is $n_{ij}\mu_{ij}(1 - \mu_{ij})$ and $\phi = 1$. However, if $n_{ij} > 1$, it is possible that the empirical variances are larger or smaller than the model-implied variances. Such overdispersion or underdispersion can be accommodated by estimating ϕ as a free parameter in a so-called quasi-likelihood approach. In likelihood or Bayesian methods, overdispersion is instead induced by including additional random effects varying over level-1 units. Note that there is no such thing as overdispersion or underdispersion if $n_{ij} = 1$, although researchers sometimes attempt to model it.

Latent response formulation

In econometrics and psychometrics, models for binary responses are often specified by imaging an underlying or latent continuous response y_{ij}^* such that the observed response y_{ij} is 1 if the latent response exceeds 0 and y_{ij} is 0 otherwise. An obvious interpretation of y_{ij}^* in the proficiency example is as a continuous measure of reading achievement that must exceed a threshold for the student to be proficient. A linear mixed model is then specified for the latent response

$$y_{ij}^* = \eta_{ij} + e_{ij}$$

If a logistic distribution is assumed for e_{ij} we obtain a logistic regression model, and, if a standard normal distribution is assumed, we obtain a probit regression model.

A simple latent response model with $\eta_{ij} = \beta_0 + \beta_1 x_{ij}$ is shown in the lower portion of **Figure 2**. The density curves represent the distribution of y_{ij}^* for different values of x_{ij} , with means falling on the upward sloping regression line. The threshold 0 is indicated by the dashed horizontal line, and the areas under the density curves exceeding this threshold are shaded. These probabilities that y_{ij}^* is greater than 0 represent the corresponding probabilities that $y_{ij} = 1$. The upper portion of the figure is a graph of these probabilities as a function of x_{ij} and we can recognize the familiar logistic curve. The logistic regression model can thus either be specified through a logit link or using a latent response formulation.

The latent response formulation can be useful for interpreting the random part of the model. For a random intercept model, we can express the within-cluster dependence as the residual intraclass correlation among the latent responses, given the covariates

$$\text{cor}(y_{ij}^*, y_{ij}^* | \mu_{ij}, \mu_{ij}) = \frac{\psi}{\psi + \text{Var}(e_{ij})}$$

Figure 2 Illustration of the relationship between latent-response model and probability of observed response being 1. Reproduced by permission of the publisher from Rabe-Hesketh, S. and Skrondal, A. (2008). *Multilevel and Longitudinal Modeling Using Stata*, 2nd edn. College Station, TX: Stata Press. Copyright 2008 by StataCorp LP.

where $\text{Var}(e_{ij})$ is $\pi^2/3$ in logistic models and 1 in probit models. For the estimates in **Table 1**, the residual intraclass correlation of the latent responses is estimated as 0.08. Hence, 8% of the residual variance in underlying reading achievement is due to schools. Although this intraclass correlation relies on the concept of a latent response, it is preferable to the correlation among the observed responses which depends on the covariate values.

Counts

Sometimes a response variable is a count of some event such as the number of days a student is absent from school in a year or the number of times a teacher shouts in an hour. The conditional response distribution is typically specified as Poisson,

$$y_{ij} | \mu_{ij} \sim \text{Poisson}(\mu_{ij})$$

and a log link is used

$$\log(\mu_{ij}) = \eta_{ij}$$

The log link ensures that the expected count is nonnegative and produces a multiplicative model for the expected count.

The variance function is $V(\mu_{ij}) = \mu_{ij}$ and $\phi = 1$. Overdispersion or underdispersion can be accommodated by estimating ϕ as a free parameter, and overdispersion can be modeled by including additional random effects varying over level-1 units. The Poisson model cannot be specified through a latent response formulation.

Other Response Types

Ordinal responses include Likert scales for agreement with attitude statements (e.g., disagree, neither agree nor disagree, and agree) and reported frequencies of doing something such as helping children with homework (e.g., daily, several times per week, occasionally, and never). The most common models are so-called cumulative logit or probit models, and these can be specified as logit or probit models for the probabilities of exceeding each of the ordered categories (except the last). A parallel regression assumption is usually made by allowing only the intercept to take different values for different categories. The models can alternatively be specified using a latent response formulation with several, freely estimated thresholds.

Discrete time durations are often of interest in education. Examples include number of semesters before dropout from college, age at which children first enter preschool, and number of years teachers teach at a school. A popular model for analyzing discrete time durations is the continuation ratio logit model. After expanding the data appropriately, this model can be estimated using logistic regression for binary responses.

Unordered categorical data arise when people choose among different alternatives, such as community college, 4-year college, or no higher education after graduation from high school. Multinomial logit models are typically used for such data.

Conditional and Marginal Relationships

The regression coefficients in generalized linear mixed models represent conditional effects in the sense that they express comparisons holding the cluster-specific random effects (and covariates) constant. For this reason, conditional effects are sometimes referred to as cluster-specific effects. In contrast, marginal effects can be obtained by averaging the conditional expectation μ_{ij} over the random effects distribution. Marginal effects express comparisons of entire sub-population strata defined by covariate values and are sometimes referred to as population-averaged effects.

In linear mixed models (identity link), the regression coefficients can be interpreted as either conditional or marginal effects. However, conditional and marginal effects differ for most other link functions. This can easily be seen for a random intercept logistic regression model with a single covariate in **Figure 3**. The cluster-specific, conditional relationships are shown as dotted curves with horizontal shifts due to different values of the random intercept. The population-averaged, marginal curve is obtained by averaging the conditional curves at each value of x_{ij} . We see that the marginal curve resembles a logistic curve with a smaller regression coefficient. Hence, the marginal effect of x_{ij} is smaller than the conditional effect.

Figure 3 Conditional relationships (dotted curves) and marginal relationship (solid curve) for a random intercept logistic model. From Skrondal, A. and Rabe-Hesketh, S. (2004). *Generalized Latent Variable Modeling: Multilevel, Longitudinal, Structural Equation Models*, Boca Raton, FL: Chapman and Hall/CRC.

The difference between conditional and marginal relationships is also visible in **Figure 1**, but it is much less pronounced due to the relatively small estimated random intercept variance.

Estimation and Software

The model parameters to be estimated in most generalized linear mixed models are the fixed regression coefficients and the covariance matrix of the random effects (the variance ψ for a random-intercept model). The most commonly used estimation methods are maximum likelihood, penalized quasi-likelihood (PQL-1), and Markov chain Monte Carlo (MCMC).

Maximum likelihood estimation is not straightforward for generalized linear mixed models because the likelihood involves integrals that cannot be solved analytically. Many software packages therefore use numerical integration, typically adaptive or ordinary Gauss-Hermite quadrature. Examples include the Stata programs `xtlogit`, `xtpoisson`, `xtmelogit`, `xtmepoisson`, and `gllamm`; the SAS procedure `NLMIXED`; and the R-program `glmer`. The estimates in **Table 1** and the predictions for **Figure 1** were obtained using `gllamm` (see multimedia).

Numerical integration is time consuming, particularly if the model includes several random effects. Approximate methods have therefore been suggested, including PQL-1 which is implemented in the SAS procedure `GLIMMIX`, the S-PLUS or R function `glmmPQL`, and the standalone programs `HLM` and `MLwiN`. Unfortunately, these methods sometimes produce biased estimates, in particular for binary responses, small cluster sizes and large intraclass correlations of the latent responses. More accurate approximations have therefore also been implemented (PQL-2 in `MLwiN` and `Laplace6` in `HLM`). Software implementing MCMC for Bayesian estimation includes the general program `BUGS` or `WINBUGS` and the program `MLwiN` which is custom made for generalized linear mixed models.

Assigning Values to Random Effects

It is sometimes required to assign values to the random effects for individual clusters. For instance, random intercepts for schools or teachers in models for student outcomes can sometimes be viewed as measures of effectiveness since they represent the school- or teacher-specific value added taking into account observed covariates such as the prior achievement of students at intake.

If MCMC is used for estimation, there is no real distinction between parameters and random effects, and estimates of the latter are obtained in a straightforward

manner. If maximum likelihood or approximate methods are used for estimation, the parameters (typically the fixed regression coefficients and the covariance matrix of the random effects) are treated as known and replaced by their estimates for the purpose of assigning values to the random effects. The random effects are then either estimated by maximum likelihood or predicted using empirical Bayes.

Viewing the random effects as the only unknown parameters, they can be estimated by maximizing the joint probability distribution (or likelihood) of the responses, given the random effects and covariates, with respect to the random effects. This maximum likelihood estimation is performed independently for each cluster. In linear mixed models, such estimates are also known as ordinary least squares (OLS) estimates.

In empirical Bayes prediction of the random effects, we exploit the information that we have about the random effects before looking at the data for a cluster, namely the estimated random effects distribution, known as the prior distribution. The posterior distribution of the random effects for a cluster is proportional to the product of the prior distribution and the likelihood for the cluster. The mean of the posterior distribution is called the empirical Bayes predictor. In linear mixed models, these predictions are also known as best linear unbiased predictors (BLUPs).

The empirical Bayes predictions tend to shrink to zero compared with the maximum likelihood estimates. This shrinkage occurs because the prior distribution has its mean at zero. The shrinkage is negligible when the likelihood dominates the prior, for instance due to a large cluster size, but can be pronounced for small cluster sizes. Empirical Bayes predictors have lower mean squared prediction errors than maximum likelihood estimators and are, therefore, usually preferred.

There are generally no closed-form expressions for the empirical Bayes predictor except for linear mixed models. For other generalized linear mixed models, empirical Bayes predictions can be obtained by numerical integration.

Some Extensions

We have considered two-level models in this article which are applicable for typical educational datasets where students are nested in schools or where repeated observations on students over time are nested in students. There are often further levels of nesting. For instance, we may have repeated observations nested within students who are nested in schools. Alternatively, students may be nested in classrooms nested in schools, or schools may be nested in school districts or countries. In these cases, we can include random effects at each of the nested levels. More complex designs require crossed random effects.

For instance, in longitudinal studies, students may be in middle school in the first two waves and, subsequently, high school in the next two waves. Middle schools are typically crossed with high schools in the sense that all students from a given middle school do not attend the same high school (or vice versa).

Estimation of models with nested random effects is not much more complex than estimation of standard generalized linear mixed models. In contrast, estimation of models with crossed random effects remains a challenge, except in linear mixed models.

The random part of the linear predictor in generalized linear mixed models is quite restrictive because each random effect ζ_{pj} merely multiplies an observed variable x_{pij} in the reduced form. Generalized linear latent and mixed models (GLLAMMs) extend generalized linear mixed models by allowing the random effects to be multiplied by different parameters for different responses. Furthermore, the random effects can be regressed on observed covariates and other random effects (at the same or higher hierarchical levels). This is useful for incorporating measurement models, such as IRT models, within generalized linear mixed models.

Generalized Linear Models

J J Faraway, University of Bath, Bath, UK

© 2010 Elsevier Ltd. All rights reserved.

Introduction

Linear models are a way of describing a response variable in terms of a linear combination of predictor variables. The response should be a continuous variable and be at least approximately normally distributed. Such models find wide application, but cannot handle clearly discrete or skewed continuous responses. Generalized linear models (GLMs) allow the extension of linear modeling ideas to a wider class of response types, such as count data or binary responses. Many statistical methods exist for such data types, but the advantage of the GLM approach is that it unites a seemingly disparate collection of response types under a common modeling methodology. Estimation, testing, and diagnostics for this class of models follow a standard path. The ideas behind GLMs were developed over many years by many researchers, but the term itself and its definition were introduced by Nelder and Wedderburn (1972) and further popularized by McCullagh and Nelder (1989).

Definition

A GLM requires the specification of two defining characteristics – the distribution of the response and the link function which describes how the mean of the response is linked to a linear combination of the predictors. The distribution is expected to belong to the exponential family of distributions which has the general form:

$$f(y|\theta, \phi) = \exp \left[\frac{y\theta - b(\theta)}{a(\phi)} + c(y, \phi) \right]$$

The θ is called the canonical parameter and represents the location while ϕ is called the dispersion parameter and represents the scale. We may define various members of the family by specifying the functions a , b , and c . The three most commonly used members of this family are the normal, Poisson and binomial distributions. For example, for a Poisson with mean μ , we have $\theta = \log(\mu)$, $\phi \equiv 1$, $a(\phi) = 1$, $b(\theta) = \exp(\theta)$, and $c(y, \phi) = -\log y!$. Other less frequently used family members are the gamma and inverse Gaussian distributions. Some other distributions, such as the negative binomial and the Weibull are not family members, but are sufficiently closely related to be used in a GLM-like manner. Other distributions might be used, but at the cost of some of the common methodology that makes GLMs attractive in the first place.

The exponential family distributions have a mean and variance that can be described in terms of the defining functions a and b :

$$\begin{aligned} EY &= \mu = b'(\theta) \\ \text{var } Y &= b''(\theta)a(\phi) \end{aligned}$$

Notice that the mean is a function of θ and so this parameter describes location while the variance is a product of functions of the location parameter and the scale parameter ϕ . $b''(\theta)$ is called the variance function and describes how the variance relates to the mean. In the normal case, $b''(\theta) = 1$ and so the variance is independent of the mean. For other distributions, the variance changes with the mean.

The effect of the predictors on the response is expressed through a linear predictor:

$$\eta = \beta_0 + \beta_1 x_1 + \cdots + \beta_p x_p = x^T \beta$$

Note that the predictors x_i might involve transformation or combinations of the original raw predictors. Furthermore, categorical predictors can be represented using indicator variables. This allows great flexibility in the representation of the effect of the predictors on the response.

The link function, g , describes how the mean response, $EY = \mu$, is linked to the covariates through the linear predictor:

$$\eta = g(\mu)$$

Any monotone continuous and differentiable function as a choice of g could suffice, but there are some convenient and common choices for the standard GLMs.

For the normal linear model, the identity link, $\eta = \mu$, is almost always used and the resulting GLM is just a standard linear model. For nonidentity g , $y = g^{-1}(x^T \beta) + \varepsilon$. This is not the same as a transform on the response ($g(y) = x^T \beta + \varepsilon$) or the commonly used transformations on the predictors. This is sometimes called a single index model, when g is estimated, not specified.

For the Poisson GLM, the mean μ must be positive. Using an identity link $\eta = \mu$ is not desirable because η can be negative. Using a log link so that $\mu = e^\eta$ ensures $\mu > 0$. This log link means that additive effects of x lead to multiplicative effects on the response. Other choices of link are very rarely used for the Poisson.

For the binomial GLM, let Y have probability of success μ in n trials. If we take the proportion Y/n as the

response, then $EY/n = \mu$. We need a link function that enforces $0 \leq \mu \leq 1$. There are several commonly used ways to ensure this, the logit link being the most frequently used, where $\eta = \log(\mu/(1 - \mu))$. The probit, $\eta = \Phi^{-1}(\mu)$ where Φ is the normal cumulative distribution function, also enjoys some use.

Every major statistical software package has code to fit GLMs. The user is simply required to specify the response type and the link function, along with the specific form of the linear predictor. Thus, knowledge of the theory of GLMs is not essential to use them in practice, but it is important to make an appropriate selection of distribution and link and understand the consequences of that choice.

Inference

The parameters, β , of the linear predictor of a GLM are usually estimated using maximum likelihood. Assuming independent observations, the log-likelihood is

$$\sum_i \left[\frac{y_i \theta_i - b(\theta_i)}{\phi} + c(y_i, \phi) \right]$$

where $a_i(\phi) = \phi$. For the normal linear model, the maximum likelihood estimate (MLE) is just the usual least-squares solution. For other MLEs numerical optimization is required. Typically, an iteratively reweighted least-squares method is used. In most cases, the convergence is rapid. A failure to converge is often a sign of some problem with the model specification or an unusual feature of the data. Estimates of variance of the regression coefficients may be obtained from

$$\text{var}(\hat{\beta}) = (X^T W X)^{-1} \hat{\phi}$$

which is comparable to the form used in weighted least squares.

Hypothesis testing for GLMs can be expressed in terms of comparisons of nested models – a larger model and a smaller model, which usually consists of a subset of the predictors found in the larger model. The smallest model we might consider uses no predictors at all, meaning that we fit a common mean μ for all responses, that is, one location parameter only. This is called the null model.

The largest model we might consider fits the response exactly. Typically, we would need to use n parameters for n data points. This can be achieved in various ways and is called the saturated or full model. This model tells us no more than the data itself and is thus usually uninformative, but it does provide a good baseline for other models.

Suppose we compare the model of current interest to the full model by using the likelihood ratio statistic which is twice the difference in the log-likelihoods of the two

models. This is also called the (scaled) deviance which takes the form:

$$\sum_i 2(y_i \tilde{\theta}_i - \hat{\theta}_i) - b(\tilde{\theta}_i) + b(\hat{\theta}_i)) / \phi$$

where $\tilde{\theta}$ are the estimates under the full (saturated) model and $\hat{\theta}$ are the estimates under the model of interest. This can be written as $D(y, \hat{\mu}) / \phi$ where the numerator is the deviance and the ϕ is the scaling. Deviances for the common GLMs are shown in **Table 1**.

Pearson's X^2 statistic

$$X^2 = \sum_i \frac{(y_i - \hat{\mu}_i)^2}{\text{var}(\hat{\mu}_i)}$$

is an alternative measure of discrepancy that is sometimes used in place of the deviance.

The scaled deviance or indeed the Pearson's X^2 statistic can be viewed as a goodness-of-fit statistic. Provided the model is correct, the scaled deviance and the Pearson's X^2 statistic are both asymptotically χ^2 with degrees of freedom equal to the number of identifiable parameters. For GLMs that have a dispersion parameter, ϕ , this test statistic is not directly usable because we do not know the value of this parameter and, absent any replication in the data, we cannot estimate in a way that is not dependent on the current model. However, for the two important cases of the Poisson and binomial, $\phi = 1$ and the test can be used. Unfortunately, the accuracy of the asymptotic approximation is dubious for smaller datasets. For a binary, that is a 0–1 response, the approximation is worthless.

For comparing a larger model, L , to a smaller nested model, S the difference in the scaled deviances, $D_S - D_L$ is asymptotically χ^2 with degrees of freedom equal to the difference in the number of identifiable parameters in the two models. For the normal model and other models where the dispersion ϕ is usually not known, this test cannot be directly used. However, if we insert an estimate of ϕ we may compute an F -statistic of the form

$$\frac{(D_S - D_L) / (df_S - df_L)}{\hat{\phi}}$$

where $\hat{\phi} = X^2 / (n - p)$ is a good estimate of the dispersion. For the normal model, $\hat{\phi}$ is the residual sum of

Table 1 For the binomial y_i is distributed $\text{Bin}(m_i, p_i)$ and $\mu_i = m_i p_i$.

GLM	Deviance
Gaussian	$\sum_i (y_i - \hat{\mu}_i)^2$
Poisson	$2 \sum_i [y_i \log(y_i / \hat{\mu}_i) - (y_i - \hat{\mu}_i)]$
Binomial	$2 \sum_i [y_i \log(y_i / \hat{\mu}_i) + (m_i - y_i) \log((m_i - y_i) / (m_i - \hat{\mu}_i))]$

For the Poisson, the deviance is known as the G-statistic. The second term $\sum_i (y_i - \hat{\mu}_i)$ is usually zero if an intercept term is used in the model.

squares for the smaller model divided by its degrees of freedom, and the resulting F -statistic has an exact F distribution for the null. For other GLMs with free dispersion parameters, the statistic is only approximately F distributed.

For every GLM except the normal, an approximate null distribution must be used whose accuracy may be in doubt particularly for smaller samples. However, the approximation is better when comparing models than for the goodness-of-fit statistic.

We may also take a Wald test approach. For a single parameter β_j , we may use the standard error of the estimate to construct a z -statistic of the form $\hat{\beta}_j/se(\hat{\beta}_j)$. This has an asymptotically normal null distribution. This is only an approximate test except in the special case of the normal GLM where the z -statistic is the t -statistic and has an exact t -distribution. The difference-of-deviances test is preferred to the Wald test.

As with standard linear models, it is important to check the adequacy of the assumptions that support the GLM. The diagnostic methods for GLMs mirror those used for normal linear models. However, some adaptations are necessary and, depending on the type of GLM, not all diagnostic methods will be applicable.

Residuals represent the difference between the data and the model and are essential to explore the adequacy of the model. In the normal case, the residuals are $\hat{e} = y - \hat{\mu}$. These are called response residuals for GLMs, but since the variance of the response is not constant for most GLMs, some modification is necessary. We would like residuals for GLMs to be defined such that they can be used in a similar way as in the normal linear model.

The Pearson residual is comparable to the standardized residuals used for linear models and is defined as

$$r_p = \frac{y - \hat{\mu}}{\sqrt{\text{var}(\hat{\mu})}}$$

These are just a rescaling of $y - \hat{\mu}$. Notice that $r_p^2 = X^2$ and hence the name. Pearson residuals can be skewed for non-normal responses. The deviance residuals are defined by analogy to Pearson residuals. The Pearson residual was r_p such that $\sum r_p^2 = X^2$, so we set the deviance residual as r_D such that $\sum r_D^2 = \text{deviance} = \sum d_i$.

Examples

Consider the (hypothetical) data shown in **Table 2** from six classrooms of 25 students each. We record the numbers of students that pass a test in each classroom along with information about a measure of average socioeconomic status and which of two teaching methods were used. It is natural to consider the response as binomially distributed with 25 trials in each case. This would require the assumptions that each student in a given classroom had

Table 2 Data showing the number (pass) of students out of 25 passing a test, socioeconomic status (ses), and teaching method (mth) used

Pass	Ses	Mth
10	1	0
20	2	1
15	3	0
21	4	1
20	5	0
24	6	1

an equal chance of passing the test and that the outcomes within a classroom were independent. It would be reasonable in practice to suspect the validity of these assumptions, but we shall proceed regardless. Heterogeneity in the probabilities would lead to the phenomenon of dispersion, for which modeling techniques exist. We choose a logit link function for this binomial GLM. It is difficult to verify any choice of link function without substantial homogeneous data. In this example, it is an unverifiable, but most common and reasonable choice. Having now specified the GLM by means of the response distribution and link function, we must select the variables for the linear predictor – we will simply take a linear combination of the two here. So our model states that pass_i is distributed $\text{Bin}(25, p_i)$ where

$$\log(p_i/(1 - p_i)) = \beta_0 + \beta_1 \text{ses}_i + \beta_2 \text{mth}_i$$

We fit this model with R software package (R Development Core Team (2008)) with the edited output shown below. Similar results can be expected with other statistical software.

Coefficients:				
	Estimate	Std. Error	z value	Pr(> z)
(Intercept)	−0.811	0.441	−1.84	0.0662
ses	0.421	0.131	3.21	0.0013
mth	1.166	0.432	2.70	0.0069

Null deviance: 26.25244 on 5 degrees of freedom

Residual deviance: 0.73718 on 3 degrees of freedom

AIC: 25.61

We see the estimated coefficients ($\hat{\beta}_0, \hat{\beta}_1, \hat{\beta}_2$) take the values (−0.811, 0.421, 1.1660). We can consider the residual deviance of 0.737 as a goodness-of-fit statistic. This should be compared to a χ^2_3 . Since the statistic is not large on this scale, we would conclude that the model does not lack for fit, and so we would probably not want for a more complex model than this. The null deviance of 26.3 is large for a χ^2_5 and so we would conclude that the null model does not fit here, that is to say children in different classrooms do not have a common probability of success. The group size of 25 is large enough that the accuracy of these tests is sufficient. Anything less than 5 for the group

sizes would make the goodness-of-fit test unreliable. We can also compare the fitted model to the null model by taking the difference in the deviances. This gives a test statistic of $26.25 - 0.74 = 25.51$ which is large for a χ^2_2 (two degrees of freedom difference between the two models). So we would prefer the fitted model to the simpler null model in this case.

We can test the significance of the individual predictors in two ways. For example, consider the teaching method. The z -statistic is 2.70 with a p -value of 0.0069, indicating a clearly significant result. However, we would prefer to test this hypothesis by fitting the appropriate smaller model, that is the one without the method variable. This has a residual deviance of 8.52 on four degrees of freedom. The difference in deviances is then $8.52 - 0.74 = 7.78$ on one (i.e., $4-3$) degree of freedom. Using the χ^2_1 , this yields a p -value of 0.005. Although the results are much the same and the second test requires a little more work, the accuracy of the latter test is significantly better, especially with sparser data. To interpret the size of the effect, it is best to use an odds scale. Thus, we can say that the use of the teaching method coded as one increases the odds of a pass by a factor of $\exp(1.166) = 3.21$ relative to the method coded as zero.

We can compute the deviance residuals as respectively

− 0.039 0.384 − 0.115 − 0.670 0.185 0.304

We do not expect deviance residuals for a binomial GLM to follow a standard normal distribution, but we might remark upon cases that exceed three in absolute value. In this case, there is nothing remotely like an outlier to concern us. For a more interesting data set we might proceed with the diagnostic methods used in standard linear models, but this example is too small to warrant further investigation.

Let us consider another example using the (hypothetical) data shown in **Table 3**. The number of incidents in eight schools are shown along with their size in numbers of students and an average school test score. We would like to know if the number of incidents is related to the test score. However, larger schools will generate more incidents and so this requires some adjustment.

The response is a count and best modeled as a Poisson. One might be tempted to model the number of incidents out of the school size as binomial, but it might not be reasonable to think that the incidents are independent events generated with some probability by each student.

We will use the log link to ensure a positive mean μ with the model taking the form

$$\log \mu = \log \text{size} + \beta_0 + \beta_1 \text{score}$$

This is called a rate model. The log size term will result in multiplying the rate at which the incidents occur by the number of students as we might wish here. Notice that this term has no regression coefficient (or we might say it is fixed at one). Such a fixed term is called an offset. The remaining part of the predictor is linear in the score. We fit this model using R although much the same results would be expected with other software. The summary results show

Coefficients:

	Estimate	Std. Error	z value	Pr(> z)
(Intercept)	−4.6703	0.5319	−8.78	<2e−16
Score	−0.0139	0.0114	−1.22	0.22

Null deviance: 8.0380 on 7 degrees of freedom

Residual deviance: 6.4944 on 6 degrees of freedom

AIC: 33.97

The negative coefficient for score of -0.0139 shows that the rate of incidents decreases with increasing test scores. We might take the z -statistic of -1.22 to test the significance of this effect giving a p -value of 0.22. However, as before, it is better to use the difference of deviance to make the test. Here the null model is the appropriate smaller model so we may compute the test statistic as $8.04 - 6.49 = 1.55$ which yields a p -value of 0.21 using a χ^2_1 , as there is one degree of freedom difference between the two models. Either way, there is insufficient evidence of an effect of test scores on the rate of incidents.

A GLM approach can also be useful for modeling categorical data as seen in this example taken from Faraway (2006). In **Table 4**, we see subjects from the 1996 US NES study cross-classified by political identification (PID) and level of education.

Suppose we consider the counts as Poisson distributed with mean μ_{ij} and use a GLM with log link taking the form

$$\log \mu_{ij} = \mu_0 + \text{PID}_i + \text{education}_j$$

where the both predictors are considered as nominal (unordered) factors, each with seven levels. Then the rate at which observations fall in each of the cells will be some overall mean rate multiplied by a parameter

Table 3 Number of incidents occurring in schools of given sizes and average test scores

Incidents	7	5	1	5	2	1	5	2
Size	985	850	241	495	838	616	759	842
Score	32	74	44	20	50	73	48	36

Table 4 A subset of subjects drawn from the 1996 US NES study cross-classified by political identification and level of education

	<i>MS</i>	<i>HS dropout</i>	<i>HS</i>	<i>Some college</i>	<i>CC degree</i>	<i>BA degree</i>	<i>MA degree</i>
Strong Dem	5	19	59	38	17	40	22
Weak Dem	4	10	49	36	17	41	23
Ind Dem	1	4	28	15	13	27	20
Ind independent	0	3	12	9	3	6	4
Ind Rep	2	7	23	16	8	22	16
Weak Rep	0	5	35	40	15	38	17
Strong Rep	1	4	42	33	17	53	25

reflecting the level of party identification times another parameter representing the level of education. This is equivalent to the claim that the party identification and level of education are independent. The estimated parameters for the factor levels represent the relative proportions of observations falling in each row or column of the data. These may or may not be of interest, but they say nothing about the relationship between the two factors. In GLMs for categorical data, the interaction terms, not the main effects, are usually the center of interest because they model the dependence between the factors.

Fitting this model resulted in a deviance of 40.7 on 36 degrees of freedom. We might compare this to a model that allows dependence between the two factors. This would require a separate parameter for each cell. Since the number of parameters would equal the number of data points, the model would fit perfectly with a deviance of zero on zero degrees of freedom. Now if we compare this latter saturated model to the independence model above, we get a difference in deviance of 40.7 on 36 degrees of freedom resulting in a p -value of 0.27. Hence, we would prefer the smaller model which represents independence of the two factors.

Traditionally, the test for independence would use a Pearson's χ^2 which we might compute here as the sum of the squared Pearson residuals giving a value of 38.8 again on 36 degrees of freedom. Hence, the outcome of the test is quite similar to the deviance-based test.

The analysis so far has not used the ordinality present in both factors. One way to accommodate these within the model is by using scores. We assign scores u_i and v_j to the rows and columns such that $u_1 \leq u_2 \leq \dots \leq u_I$ and $v_1 \leq v_2 \leq \dots \leq v_J$. The assignment of scores requires some judgment. If one has no particular preference, even spacing allows for the simplest interpretation. The model becomes

$$\log \mu_{ij} = \mu_0 + \text{PID}_i + \text{education}_j + \gamma u_i v_j$$

where γ represents the amount of association and is rather like an (unscaled) correlation coefficient, $\gamma = 0$ means independence. We assigned the scores 1–7 respectively to each of the factors and fit this model. We obtained $\hat{\gamma} = 0.0287$ so the positive value indicates a positive

association although we cannot directly interpret the size of the effect. The deviance was 30.6 which represents a difference of 10.1 on just one degree of freedom from the independence model. This is a strongly significant result indicating that we have found an association here. Notice that it was essential to use the information about the ordinality of the factors to obtain this result.

Summary

Generalized linear models provide a common approach to a broad range of response modeling problems. Normal, Poisson, and binomial responses are the most commonly used, but other distributions can be used as well. Apart from specifying the response, GLMs also need a link function to be set which allows further flexibility in the modeling. The GLM can be fitted using a common procedure and a mechanism for hypothesis testing is available. Diagnostics using deviance residuals provide a way to check that chosen models are adequate.

Use of a GLM is by no means sufficient as there are aspects of analysis of all the different GLMs which are specific to that particular response type. For example, while a logistic regression is a GLM the user still needs to understand the particular interpretation of odds in this type of model. With categorical data, the imposition of a GLM sometimes requires parametrizations that are difficult to interpret and other approaches may be more revealing. Thus while GLMs might provide some convenient structure across seemingly different models, we must recognize that they do not provide a comprehensive solution.

The basic GLM has been extended in many directions. Wedderburn (1974) introduced the idea of quasi-likelihood, which avoids explicitly specifying the distribution of the response, requiring only that we specify the link and variance functions. This idea was extended to the notion of generalized estimating equations with particular application to longitudinal data by Liang and Zeger (1986). Lindsey (1997) gives a wide range of applications of GLMs while Fahrmeir and Tutz (2001) describe GLMs for multivariate responses.

Further reading about GLMs can be found in several books. McCullagh and Nelder (1989) is the classical reference although this can be difficult for readers without a background in statistical theory. Gill (2001), Fox (2008), and Dobson and Barnett (2008) provide more accessible texts. Faraway (2006) has an introduction to GLMs based on R software and Hardin and Hilbe (2007) has a text based on Stata.

Generating Random Numbers

P J Pashley and A Amodeo, Law School Admission Council, Newtown, PA, USA

© 2010 Elsevier Ltd. All rights reserved.

Educational research has a long history of employing random numbers. Before the advent of computers, the random number sequences needed were typically relatively short, utilized primarily within experimental designs that required random assignment of conditions to subjects (e.g., type of instruction delivered in classrooms) or vice versa. The need for these short random number sequences continues today, and they can be found in many of the same places as in the past, such as in the appendices of books on statistical methods, as well as now on the Internet.

Access to ever-increasing computer processing power and availability has ushered in an era of progressively more sophisticated statistical models, analysis tools, and other empirical procedures. Associated estimation and simulation methods can require very large sequences of random numbers. For example, consider the task of simulating correct and incorrect responses from an administration of the Law School Admission Test (LSAT). This assessment currently consists of about 100 multiple-choice items and is routinely administered to samples of approximately 50 000 test-takers at one time. Given model parameters that specify item characteristics and test-taker abilities, 5 million random numbers are needed to simulate a response for each item–test-taker combination. If these responses are used to form the basis for estimating statistics, such as the standard error of equating, many (i.e., tens or hundreds) of these random sets could be required.

The National Assessment of Educational Progress (NAEP) program provides a good case study for the variety of ways in which random numbers are employed in educational research. This is a nationally representative assessment of student achievement in the United States, conducted periodically within a number of subject areas. To ensure representativeness, probability samples of schools and students are randomly selected. For quality-control purposes, random samples of booklets and corresponding scores are routinely picked and inspected for errors during the assessment cycles. For reporting purposes, instead of calculating individual ability estimates, probability distributions of student proficiencies are estimated first, conditional on item responses and background variables. Then for each student in the assessment, five random draws (called plausible values) from a suitably estimated probability distribution are performed. These plausible values are subsequently used to estimate group score statistics and their related variances. For operational research purposes, large-scale simulations, employing millions of

random numbers, are routinely performed to study current and potential future assessment methodology (e.g., see Bennett, 2008). For further details on how the NAEP program makes use of random numbers, their website can be referenced.

This article presents aspects of the generation of long sequences of random numbers, including various types of generating algorithms and the properties of the sequences they yield. Researchers should be aware that their study results can be tainted by employing an inadequate random number generator (RNG). These substandard generators have been and continue to be made readily available to unsuspecting users through some software packages. Before the good and bad qualities of RNGs are addressed, however, the nature of random numbers is discussed.

True Random Numbers

Readers interested in an extended and complete theoretical and philosophical discussion of what a random sequence is should refer to Knuth (1998). For our purposes, we will simply define a true random number as a single unpredictable outcome from a random experiment. To be useful, all the possible events and their corresponding probabilities that constitute the random experiment are usually assumed to be known. For example, one toss of a fair coin (the random experiment) will yield a head or a tail (the possible events). The specific outcome of one coin toss will be unpredictable, even though we know the chance of a head or tail (the event probabilities) is 50/50. In other words, it is not sufficient for random numbers to be unpredictable: to be useful, they must also conform to a known sampling distribution.

Repeated tossing of a fair coin will yield a sequence of random numbers, each of which will constitute an independent observation from a random experiment. In other words, for any particular toss, the results of previous and subsequent tosses will have no impact on the likelihood of a head or tail outcome. Therefore, if a fair coin is tossed 99 times and 99 heads are observed, the chances of a head appearing on the 100th toss will still be 50/50.

While the tossing of coins to produce large sequences of random numbers is clearly impractical, efficient tools for measuring and recording other (seemingly) random physical events have been developed. For example, the ZRANDOM USB generator samples thermal electronic noise to produce random numbers that can be fed into a

computer by way of a universal serial bus (USB) port. Alternatively, large random sequences can be downloaded from websites such as <http://www.random.org> and <http://www.fourmilab.ch/hotbits>, which also employ physical events to produce random numbers (radio noise and radioactive decay, respectively).

Providers of these types of sequences usually claim that they are providing true random numbers. However, just as no truly fair coins exist, all measures of physical events will exhibit some, although hopefully inconsequential, amounts of bias (i.e., departures from the assumed underlying sampling distribution). Researchers are urged to independently test all sequences they use for randomness (see below for more details), regardless of whether they are labeled as true random numbers or not.

Random Number Distributions

Most basic RNGs simulate uniformly distributed random numbers (or uniform variates) that range between zero and one. A theoretical uniform distribution is defined to be continuous over an interval, with endpoints assumed here to be zero and one. In practical terms, however, random numbers are typically output or stored with a relatively small number of decimal places (e.g., six). Therefore, instead of a continuum, one can think of a finite, although very large, number of discrete points between zero and one that the generated random numbers can assume. Under these practical constraints, there should be an equal probability that a generated random number can assume any of the possible discrete points that span the distribution.

Output from uniform RNGs can be categorized into smaller groupings for various purposes, such as simulating the tossing of a coin (e.g., by categorizing random numbers less than 0.5 as heads and those greater than or equal to 0.5 as tails). Simulations of student behavior can be undertaken in a similar fashion. For instance, returning to the LSAT example given earlier, correct and incorrect responses can be simulated by first estimating the probability that test-takers will answer individual items correctly, usually by employing an item response theory (IRT) model. Then individual responses can be simulated by comparing a uniform variate, say the k th number (denoted by u_k) in the generated sequence, to the probability of test-taker i answering item j (estimated to be p_{ij}) as follows:

set the simulated response to correct if $u_k < p_{ij}$; otherwise,
set the simulated response to incorrect.

If random sequences from other distributions are required, uniformly distributed random number sequences are commonly first generated and then transformed into the desired variants. For example, the Box–Muller

transformation (Box and Muller, 1958) can be applied to two uniform variates (u_1 and u_2) to produce two independent univariate standard normal variates (n_1 and n_2) by assigning

$$n_1 = \sqrt{-2\ln u_1} \cos(2\pi u_2), \text{ and } n_2 = \sqrt{-2\ln u_1} \sin(2\pi u_2).$$

Note that the arguments of the $\cos(\bullet)$ function are in radians.

Gentle (2003) provides a thorough review of methodology available to generate random numbers that follow most commonly used univariate and multivariate distributions, along with more general approaches that are applicable to any type of theoretical distributional assumptions.

Deterministic Generation Methods

A required feature of the random sequences used in many educational research studies is that they be reproducible. This allows a researcher to rerun his or her simulation exactly and allows other independent researchers the ability to replicate the study. Because of the unpredictable process by which they are generated, random sequences yielded by physical events must be stored if they are to be reused. These databases can be quite large, and sharing them can be cumbersome.

As a convenient alternative, methods that generate random number sequences algorithmically, called deterministic methods, can be employed. In order to reproduce the sequences these generators yield, they simply need to be rerun with the same initial values. They can also be easily shared with others by listing the algorithm the generator is based on or by providing related software code.

Because of their deterministic nature, the sequences of numbers that these types of generators produce cannot be thought of as truly random. However, for practical purposes, if the sequences produced by a deterministic method adhere sufficiently to the properties of truly (i.e., theoretical) random sequences, they can legitimately be employed in their stead. These types of deterministic generators are often referred to in the literature as pseudorandom number generators. However, we will simply call them RNGs here, given the fact that the ultimate goal of any RNG, including deterministic ones, is to generate sequences of numbers that are indistinguishable from those we would expect to obtain from a true RNG, if one existed. Unfortunately, some early RNGs fell well short of achieving that goal.

An early and extensively studied type of RNG, called the multiplicative congruential generator (MCG), was suggested by D. H. Lehmer (1951). Every new value (x_{j+1}) it generates is a result of the following simple

mathematical manipulation on the previously generated value (x_j):

$$x_{j+1} = (ax_j) \bmod m,$$

where m is the modulus, with $m > 0$; and a is the multiplier, with $0 \leq a < m$.

The mod function finds remainders as follows:

$$(x) \bmod m = x - m\text{FLOOR}(x/m)$$

where the FLOOR(\bullet) function yields the largest integer less than or equal to the given argument.

To begin the sequence, a starting value or seed is chosen, usually denoted as x_0 (with $0 \leq x_0 < m$). Uniform variates (u_j 's) can be derived from the generated values (x_j 's) by dividing them by the modulus:

$$u_j = x_j / m$$

To illustrate a simple MCG, let $x_0 = 7$, $a = 7$, and $m = 10$. The resultant sequence, including the seed, is

$$7, 9, 3, 1, 7, 9, 3, 1, 7, 9, 3, 1, \dots$$

and the related uniform variates are

$$.7, .9, .3, .1, \dots$$

In this example, note that the MCG starts repeating itself after only four values. The length of the repeating cycle, in this case four, is called the period.

Because of its relative mathematical simplicity, many analytical results are available for MCGs. For example, it is known that an MCG has a period of m if and only if:

1. $a - 1$ is a multiple of p for every prime p dividing m ; and
2. if m is a multiple of 4, then $a - 1$ must also be a multiple of 4.

For details on this and other theoretical MCG properties, readers can refer to Knuth (1998).

One unfortunate property that all MCGs possess is that if their sequences, after being assigned to n -tuples, are viewed as points in an n -dimensional cube, all the points will be found to lie on a relatively few parallel hyperplanes (Marsaglia, 1968). To illustrate this type of phenomenon, consider the case of the (once) widely used IBM SYSTEM/360 (1968) RANDU generator. It was essentially defined by a multiplier and modulus with values 65 539 and 2^{31} , respectively. These specifications were used to generate 6000 uniform variates that were combined sequentially into 2000 independent three-tuples:

$$(u_1, u_2, u_3), (u_4, u_5, u_6), \dots, (u_{5998}, u_{5999}, u_{6000}).$$

Figure 1 provides five views of these 2000 generated three-dimensional points plotted within a unit cube. The five views were created by inducing successive vertical rotations and horizontal tilts. Note that views (a) and (e) appear two-dimensional simply because of the orientation

Figure 1 Five views of a unit cube containing 2000 random points, with degree of vertical rotation (R) and horizontal tilt (T) indicated.

of the cube. Ideally, these 2000 points should be randomly scattered throughout the cube, as they appear to be in views (a), (b), and (e). However, views (c) and (d) clearly show that the points actually line up on 15 hyperplanes.

Gentle (2003) provides a good review of other classes of uniform RNGs, including multiple recursive generators such as the lagged Fibonacci congruential generator, matrix-based generators, and nonlinear congruential generators. These have all been investigated analytically and empirically to varying degrees, although none more than the MCG. All have their strengths and weaknesses. A way to address the weaknesses inherent in a single RNG is to combine it with one or more other RNGs into a composite RNG.

One approach to combining two RNGs is called shuffling, whereby one of the generators is used to produce a random sequence and a second is used to reorder the sequence. A different approach entails generating a random sequence of pairs of uniform variates using two separate RNGs, and then choosing one value from each pair using a third RNG to yield the final random sequence. No matter how multiple RNGs are integrated, it appears wise to combine different classes of RNGs into composites. For example, combining two MCGs into a composite might actually exacerbate certain problems rather than solve them.

A type of RNG that has become widely used is the Mersenne twister (Matsumoto and Nishimura, 1998). Along with good empirical randomness results, their type of generator boasts very long periods (e.g., the version MT19937 has a period of $2^{19,937} - 1$). Researchers

who intend to run very extensive simulations should be aware of the period of the RNG they are employing to avoid the possibility of repeat sequencing. Note, however, that long periods do not necessarily guarantee better results in terms of randomness.

The book *Numerical Recipes: The Art of Scientific Computing* (Press *et al.*, 2007) is a good source for descriptions of reasonable RNGs and software for implementing specific versions of them. The authors also discuss approaches to producing variates from nonuniform distributions and provide the software to generate them.

Tests of Randomness

As indicated earlier, problems with many widely used RNGs have been observed in the past. For some applications, these deficiencies may not be critical. However, if random numbers are the basis of an extensive simulation study, reported results could be contaminated with spurious flaws in the RNG being employed.

Researchers testing an RNG for randomness are in the enviable position of knowing the exact underlying distributional properties of the statistical tests they are conducting. This is not the case in almost all empirical educational research situations. For example, consider a simple *t*-test comparing the means from two groups. This test assumes that the means were calculated from two normal distributions whose variances are equal. While these are often reasonable assumptions to make, in real-world research situations, no one knows how closely they represent the true state of affairs.

In contrast, if an RNG is designed to yield uniform variates, for example, we know exactly how the generated sequences should behave. Therefore, we know that if an RNG fails a randomness test, it is not due to departures from underlying distributional assumptions, but rather to the failure of the RNG to conform to them.

As illustrated earlier (see **Figure 1**), graphical methods can be effective in uncovering flaws in random sequences. Besides visual confirmations of basic randomness, plots such as the residual Q-Q plot (e.g., see Chambers *et al.*, 1983) can be used to detect departures from assumed distributional properties. These types of plots are especially effective when paired with related confidence intervals, summary statistics, and significance tests (e.g., see Pashley, 1993).

As there are so many aspects to what constitutes randomness, batteries of tests should be used when assessing the quality of a particular RNG. One such suite of 18 goodness-of-fit tests called DIEHARD was compiled by Marsaglia (1985). A CD containing this suite, along with a selection of RNGs, is available from the author. The National Institute of Standards and Technology (NIST)

also recommends a battery of 16 tests that can be found at their website.

Finally, while running multiple significance tests, one should be cognizant of the overall significance level, not just those corresponding to individual tests. In other words, researchers should be aware that the chance of obtaining a false-positive finding increases with the number of separate significance tests performed.

Additional Features to Consider

While it is important for researchers to conduct a number of statistical tests to ensure that the RNG they are considering will provide adequate results in terms of distributional properties, there are a number of other features that should be evaluated. Two such attributes – the reproducibility and the period of generated random sequences – have already been discussed earlier. Three more features are presented now – portability, efficiency, and prominence – that should also be considered, especially when choosing among a number of deterministic RNGs. With this in mind, we will restrict our attention here to algorithmically produced random numbers.

Portability is an attribute that impacts on how reproducible random numbers are across different computer platforms. In other words, a portable RNG program or software code should yield the same sequences when run on different computers. This is an important feature, not only because programs are often shared among researchers, but also because individual researchers may themselves run their programs on multiple computers that they have access to at work, in a lab, or at home. In addition, programs are sometimes developed and tested on personal computers and then run more extensively on mainframe computers.

Besides affecting the reproducibility of results, lack of portability may have consequences in terms of the expected randomness of the generated sequences. That is, an RNG could pass a battery of tests on one platform, but fail some of them on a different machine. Determining the extent to which an RNG is theoretically portable at the level of machine processing (e.g., determining the effects of employing different data types, computer languages, and compilers) is a complicated undertaking. Fortunately, RNGs can be easily tested for portability across a number of different platforms by comparing generated values at the beginning and near the end of an RNG's useful cycle.

The efficiency of an RNG's algorithm in terms of time to execute should be considered, although this attribute is becoming less of a concern as the processing capabilities of computers continue to increase. That said, if one RNG produces values in half the time of another, this can translate into significant time savings when extensive

simulations are being run. The efficiencies of different RNGs can be easily compared by recording the time each takes to generate very long number sequences. One should be careful to ensure that RNGs are tested in the same manner in which they will eventually be employed in a subsequent simulation (e.g., called as a subroutine). While efficiency can be an important feature to consider, the quality of different RNGs in terms of apparent randomness should almost always trump their efficiency when users are attempting to select among them.

Finally, users choosing among available RNGs would be wise to consider their prominence in terms of how thoroughly they have been studied and reported on in the scientific literature. There is no perfect RNG that will withstand all tests for randomness. However, users of an extensively investigated RNG will know most of its potential limitations, as opposed to a newly proposed RNG that might be an improvement in some sense (e.g., longer periods), but might also contain other unstudied deficiencies.

Summary

Robert R. Coveyou once said, "The generation of random numbers is too important to be left to chance." Even casual users of RNGs should take this quote to heart. While some software packages have upgraded the resident RNGs they provide in recent versions, such as Excel 2003 and above, others have not. Users should certainly be wary of any generic-looking RNG that lacks supporting documentation that specifies the generating methodology used and the randomness tests it has passed.

The required amount of additional investigations into the adequacies of a particular RNG should be proportional to the potential impact that flawed random sequences might have on a research study. The empirical models used in educational research continue to increase in complexity, and these models often characterize large numbers of variables with elaborate interrelationships. Researchers undertaking large-scale simulation studies involving these complex models must ensure that the RNG they employ offers random sequences even when viewed at high levels of dimensionality.

When research results are reported, a description of any RNG used should be included, just as study conditions and subject attributes are normally described. The type of RNG used should be specified, including its components if it is a composite generator, along with how another researcher might obtain or run a copy of the RNG. If the RNG code was embedded in a larger simulation program, the underlying algorithm should be specified in an appendix. The types of tests or test batteries the RNG passed, or is known to have passed, should be documented.

The portability of an RNG employed in simulation studies could also be discussed (e.g., on what types of computers it was used), and reproducibility issues could be addressed by providing values from the beginning (i.e., initial values) and end of a sufficiently long generated sequence. Some indication of the RNG's cycle period would also be useful to other researchers who wish to extend simulation studies.

Regardless of whether one is a casual or high-end user of RNGs, or somewhere in-between, understanding a generator's strengths and weaknesses is important. After all, educational practice should be influenced by valid research findings, not the incidental idiosyncrasies of a flawed RNG.

Goodness-of-Fit Testing

A Maydeu-Olivares and C García-Forero, University of Barcelona, Barcelona, Spain

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Absolute goodness of fit – The discrepancy between a statistical model and the data at hand.

Goodness-of-fit index – A numerical summary of the discrepancy between the observed values and the values expected under a statistical model.

Goodness-of-fit statistic – A goodness-of-fit index with known sampling distribution that may be used in statistical-hypothesis testing.

Relative goodness of fit – The discrepancy between two statistical models.

Introduction

The goodness of Fit (GOF) of a statistical model describes how well it fits into a set of observations. GOF indices summarize the discrepancy between the observed values and the values expected under a statistical model. GOF statistics are GOF indices with known sampling distributions, usually obtained using asymptotic methods, that are used in statistical hypothesis testing. As large sample approximations may behave poorly in small samples, a great deal of research using simulation studies has been devoted to investigate under which conditions the asymptotic p -values of GOF statistics are accurate (i.e., how large the sample size must be for models of different sizes).

Assessing absolute model fit (i.e., the discrepancy between a model and the data) is critical in applications, as inferences drawn on poorly fitting models may be badly misleading. Applied researchers must examine not only the overall fit of their models, but they should also perform a piecewise assessment. It may well be that a model fits well overall but that it fits poorly some parts of the data, suggesting the use of an alternative model. The piecewise GOF assessment may also reveal the source of misfit in poorly fitting models.

When more than one substantive model is under consideration, researchers are also interested in a relative model fit (i.e., the discrepancy between two models; see Yuan and Bentler, 2004; Maydeu-Olivares and Cai, 2006). Thus, we can classify GOF assessment using two useful dichotomies: GOF indices versus GOF statistics, and absolute fit versus relative fit. In turn, GOF indices and statistics can be classified as overall or piecewise. A third

useful dichotomy to classify GOF assessment is based on the nature of the observed data, discrete versus continuous. Historically, GOF assessment for multivariate discrete data and that for multivariate continuous data have been presented as being completely different. However, new developments in limited information GOF assessment for discrete data reveal that there are strong similarities between the two, and here, we shall highlight the similarities in GOF assessment for discrete and continuous data.

GOF testing with Discrete Observed Data

Consider modeling N observations on n discrete random variables, each with K categories, such as the responses to n test items. The observed responses can then be gathered in an n -dimensional contingency table with $C = K^n$ cells. Within this setting, assessing the GOF of a model involves assessing the discrepancy between the observed proportions and the probabilities expected under the model across all cells $c = 1, \dots, C$ of the contingency table. More formally, let π_c be the probability of one such cell and let p_c be the observed proportion. Let $\boldsymbol{\pi}(\boldsymbol{\theta})$ be the C -dimensional vector of model probabilities expressed as a function of, say, q model parameters to be estimated from the data. Then, the null hypothesis to be tested is $H_0 : \boldsymbol{\pi} = \boldsymbol{\pi}(\boldsymbol{\theta})$, that is, the model holds, against $H_1 : \boldsymbol{\pi} \neq \boldsymbol{\pi}(\boldsymbol{\theta})$.

GOF Statistics for Assessing Overall Fit

The two standard GOF statistics for discrete data are Pearson's statistic

$$X^2 = N \sum_{c=1}^C (p_c - \hat{\pi}_c)^2 / \hat{\pi}_c, \quad [1]$$

and the likelihood ratio statistic

$$G^2 = 2N \sum_{c=1}^C p_c \ln(p_c / \hat{\pi}_c). \quad [2]$$

where $\hat{\pi}_c = \pi_c(\hat{\boldsymbol{\theta}})$ denotes the probability of cell c under the model.

Asymptotic p -values for both statistics can be obtained using a chi-square distribution with $C - q - 1$ degrees of freedom when maximum likelihood estimation is used. However, these asymptotic p -values are only correct when

all expected frequencies $N\hat{\pi}_c$ are large (>5 is the usual rule of thumb). A practical way to evaluate whether the asymptotic p -values for X^2 and G^2 are valid is to compare them. If the p -values are similar, then both are likely to be correct. If they are very different, it is most likely that both p -values are incorrect.

Unfortunately, as the number of cells in the table increases, the expected frequencies become small (as the sum of all C probabilities must be equal to 1). As a result, in multivariate discrete data analysis, most often, the p -values for these statistics cannot be trusted. In fact, when the number of categories is large (say $k > 4$), the asymptotic p -values almost invariably become inaccurate as soon as $n > 5$. To overcome the problem of the inaccuracy of the asymptotic p -values for these statistics, two general methods have been proposed: resampling methods (e.g., bootstrap), and pooling cells. Unfortunately, existing evidence suggest that resampling methods do not yield accurate p -values for the X^2 and G^2 statistics (Tollenaar and Mooijart, 2003). Pooling cells may be a viable alternative to obtain accurate p -values in some instances. For instance, rating items with five categories can be pooled into three categories to reduce sparseness. However, if the number of variables is large, the resulting table may still yield some small expected frequencies. Moreover, pooling may distort the purpose of the analysis. Finally, pooling must be performed before the analysis is made to obtain a statistic with the appropriate asymptotic reference distribution.

Due to the difficulties posed by small expected probabilities on obtaining accurate p -values for GOF statistics assessing absolute models, some researchers have resorted to examining only the relative fit of the models under consideration, without assessing the absolute model fit. Other researchers simply use GOF indices.

GOF Indices

With L denoting the loglikelihood, two popular GOF indices are Akaike's information criterion (AIC), $AIC = -2L + 2q$ and Schwarz Bayesian information criterion (BIC), $BIC = -2L + q \ln(N)$,

$$AIC = -2L + 2q, BIC = -2L + q \ln(N) \quad [3]$$

The AIC and BIC are not used to test the model in the sense of hypothesis testing, but for model selection. Given a data set, a researcher chooses either the AIC or BIC, and computes it for all models under consideration. Then, the model with the lowest index is selected. Notice that both the AIC and BIC combine absolute fit with model parsimony. That is, they penalize by adding parameters to the model, but they do so differently. Of the two, the BIC penalizes by adding parameters to the model more strongly than the AIC.

GOF Statistics for Piecewise Assessment of Fit

In closing this section, the standard method for assessing the source of misfit is the use of z -scores for cell residuals

$$\frac{p_c - \hat{\pi}_c}{SE(p_c - \hat{\pi}_c)}, \quad [4]$$

where SE denotes standard error. In large samples, their distribution can be approximated using a standard normal distribution. Unfortunately, the use of these residuals even in moderately large contingency tables, is challenging. It is difficult to find trends in inspecting these residuals, and the number of residuals to be inspected is easily too large. Most importantly, for large C , because the cell frequencies are integers and the expected frequencies must be very small, the resulting residuals will be either very small or very large.

New Developments in GOF with Discrete Observed Data: Limited Information Methods

In standard GOF methods for discrete data, contingency tables are characterized using cell probabilities. However, they can be equivalently characterized using marginal probabilities. To see this, consider the following 2×3 contingency table:

	$X_2 = 0$	$X_2 = 1$	$X_2 = 2$
$X_1 = 0$	π_{00}	π_{01}	π_{02}
$X_1 = 1$	π_{11}	π_{11}	π_{12}

This table can be characterized using the cell probabilities $\boldsymbol{\pi} = (\pi_{00}, \dots, \pi_{12})'$. Alternatively, it can be characterized using the univariate $\boldsymbol{\pi}_1 = (\pi_1^{(1)}, \pi_2^{(1)}, \pi_2^{(2)})$ and bivariate $\boldsymbol{\pi}_2 = (\pi_{12}^{(1)(1)}, \pi_{12}^{(1)(2)})$ probabilities, where $\pi_i^{(k)} = \Pr(X_i = k)$, $\pi_{ij}^{(k)(l)} = \Pr(X_i = k, X_j = l)$, and

	$X_2 = 0$	$X_2 = 1$	$X_2 = 2$	
$X_1 = 0$				
$X_1 = 1$		$\pi_{12}^{(1)(1)}$	$\pi_{12}^{(1)(2)}$	$\pi_1^{(1)}$
		$\pi_{(2)}^{(1)}$	$\pi_{(2)}^{(2)}$	

Both characterizations are equivalent, and the equivalence extends to contingency tables of any dimension.

Limited-information GOF methods disregard information contained in the higher-order marginals of the table. Thus, quadratic forms in, say, univariate and bivariate residuals are used instead of using all marginal residuals up to order n .

GOF Statistics for Assessing Overall Fit

Maydeu-Olivares and Joe (2005, 2006) proposed a family of GOF statistics, M_r , that provides a unified framework for limited information and full information GOF statistics. This family can be written as

$$M_r = N \hat{\mathbf{e}}_r' \hat{\mathbf{C}} \hat{\mathbf{e}}_r, \quad [5]$$

where $\hat{\mathbf{e}}_r$ are the residual proportions up to order r and

$$\mathbf{C} = \Gamma_r^{-1} - \Gamma_r^{-1} \Delta_r (\Delta_r' \Gamma_r^{-1} \Delta_r)^{-1} \Delta_r' \Gamma_r^{-1}. \quad [6]$$

Here, Γ_r denotes the asymptotic covariance matrix of the residual proportions up to order r and Δ_r is a matrix of derivatives of the marginal probabilities up to order r with respect to the model parameters. Two members of this family are, for instance, M_2 and M_m . In M_2 only univariate and bivariate residuals are used. In M_m all residuals up to order n , the number of variables, are used. When ML estimation is used, M_m is algebraically equal to Pearson's X^2 .

The asymptotic distribution of any statistic of the M_r family is chi-square with degrees of freedom (df) = number of residuals used $-q$. For the chi-square approximation to M_r to be accurate, the expected frequencies of $\min(2r, n)$ marginals need to be large. Thus, for M_m , expected cell frequencies need to be large, but for M_2 , where $r = 2$, only expected frequencies for sets of $\min(2r, n) = 4$ variables need to be large (provided $n > 4$). As a result, when only low-order margins are used, the asymptotic p -values are accurate even in gigantic models and small samples. Furthermore, often more power is obtained than when all the information available in the data is used. Consequently, Maydeu-Olivares and Joe suggest testing at the highest level of margins for which a model is identified, discarding higher-order margins. Since most models are identified using only univariate and bivariate information (i.e., they can be estimated using only univariate and bivariate information), M_2 should be the statistic of choice. For instance, the two-parameter logistic item-response theory (IRT) model is identified (it can be estimated) using only univariate and bivariate information. As a result, its fit may be tested using M_2 .

GOF Statistics for Piecewise Assessment of Fit

For a piecewise assessment of fit, z -scores for marginal residuals involving one, two, or three variables may be used (i.e., the marginal residuals divided by their SE s). It is simpler to extract valuable information from them than from cell residuals. However, when the number of categories is large, there are often too many marginal residuals. In these cases, Pearson's X^2 may be computed for pairs (or if needed, triplets of variables), provided there are enough degrees of freedom for testing. Here,

df = number of residuals used – number of estimated parameters involved. However, when used for piecewise assessment of fit, X^2 may yield an undue impression of poor fit (Maydeu-Olivares and Joe, 2006). The use of the M_r statistics in place of X^2 for pairs (or triplets) of variables solves this problem.

GOF Testing with Continuous Observed Data

GOF is a very active area of research in structural equation modeling (SEM). In classical SEM applications, multivariate models for continuous data (often involving latent variables) are estimated from some summary statistics (typically means and covariances or correlations). For ease of exposition, here we assume that the model is estimated using covariances, but the results can be easily extended to models estimated from other sets of statistics.

Let $\boldsymbol{\sigma}(\boldsymbol{\theta})$ be the $t = n(n+1)/2$ nonredundant population variances and covariances expressed as a function of q model parameters, and let \mathbf{s} be its sample counterpart. The null hypothesis to be tested is $H_0: \boldsymbol{\sigma} = \boldsymbol{\sigma}(\boldsymbol{\theta})$, that is, that the model holds, against $H_1: \boldsymbol{\sigma} \neq \boldsymbol{\sigma}(\boldsymbol{\theta})$.

GOF Statistics for Assessing Overall Fit

Two procedures can be used to obtain a GOF statistic. The first procedure is based on using the minimum of the fitted function, \hat{F} , multiplied by sample size, N , say $T = N\hat{F}$. This is the usual chi-square test in SEM. The second procedure is based on using a quadratic form in residual summary statistics.

Now, T will only be asymptotically chi-square distributed if the estimator is asymptotically efficient for the distribution of the data. Under multivariate normal assumptions, the efficient estimators are maximum likelihood (ML) and generalized least squares (GLS). Under the asymptotically distribution-free (ADF) distributional assumptions set forth by Browne (1982), the efficient estimator is weighted least squares (WLS). Thus, T is asymptotically distributed as a chi-square with $t-q$ degrees of freedom only when ML or GLS estimation is used under normality, or when WLS estimation is used under ADF assumptions. In all other cases where T is not asymptotically chi-square, its distribution may be approximated by a chi-square if T is scaled by its asymptotic mean or adjusted by its asymptotic mean and variance. These are the so-called Satorra and Bentler (1994) T_s and T_a test statistics, respectively. Thus, if a model is estimated using, for instance, unweighted least squares, T is not asymptotically chi-square, but its distribution can be approximated using a chi-square distribution using Satorra-Bentler corrections.

Regarding the second procedure, Browne (1982) proposed the residual-based statistic

$$T_B = N\hat{\epsilon}'\hat{C}\hat{\epsilon}, \mathbf{C} = \mathbf{\Gamma}^{-1} - \mathbf{\Gamma}^{-1}\mathbf{\Delta}(\mathbf{\Delta}'\mathbf{\Gamma}^{-1}\mathbf{\Delta})^{-1}\mathbf{\Delta}'\mathbf{\Gamma}^{-1}, \quad [7]$$

where $\hat{\epsilon} = \mathbf{s} - \sigma(\hat{\theta})$, $\mathbf{\Gamma}$ is the asymptotic covariance matrix of the residual covariances, and $\mathbf{\Delta}$ is a matrix of derivatives of the population covariances with respect to the model parameters. $\mathbf{\Gamma}$ may be computed under normality assumptions or under ADF assumptions. This statistic is also asymptotically distributed as a chi-square with $t-q$ degrees of freedom.

Unfortunately, when the data are not normally distributed, it has been repeatedly found in simulation studies that the p -values of Browne's statistic are inaccurate unless the number of variables is small and the sample size is very large. Recently, Yuan and Bentler (1997) have proposed a modification of T_B (with the same asymptotic distribution as T_B) whose p -values are more accurate in small samples and nonnormal data than those for T_B . This is

$$T_{YB} = \frac{T_B}{1 + NT_B/(N-1)^2}. \quad [8]$$

GOF Statistics for Piecewise Assessment of Fit

Z -scores for residuals are used for piecewise assessment of fit. The z -score for the residual covariance between variables i and j is

$$\frac{s_{ij} - \hat{\sigma}_{ij}}{\text{SE}(s_{ij} - \hat{\sigma}_{ij})}, \quad [9]$$

where $\hat{\sigma}_{ij} = \sigma_{ij}(\hat{\theta})$. Browne's and Yuan and Bentler's statistics eqns. [7] and [8] are, in fact, a test based on the joint set of residuals eqn [9].

GOF Indices

For continuous data, the AIC and BIC criteria used for model selection are GOF indices. When ML is not used, then the term $-2L$ in eqn [3] is simply replaced by T , the minimum of the estimated fit function multiplied by sample size, that is

$$\text{AIC} = T + 2q, \text{ BIC} = T + q \ln(N). \quad [10]$$

The AIC and BIC indices can be computed for any estimator, as no p -value is computed.

In addition, literally dozens of GOF indices have been proposed. Some may be used to assess the overall fit of the model under consideration, whereas others assess the relative fit of the model. A GOF index that may be used to assess the overall fit of a model is the standardized root mean residual (SRMR),

$$\text{SRMR} = \sqrt{\sum_j \sum_{k < j} \left(\frac{s_{jk}}{\sqrt{s_{jj}}\sqrt{s_{kk}}} - \frac{\hat{\sigma}_{jk}}{\sqrt{\hat{\sigma}_{jj}}\sqrt{\hat{\sigma}_{kk}}} \right)^2} / t. \quad [11]$$

The SRMR may be used to assess the average magnitude of the discrepancies between observed and expected covariances in a correlation metric. Note that there exist slightly different versions of this statistic.

Among GOF indices for relative fit assessment, two popular indices are the Tucker–Lewis index (TLI) and the comparative fit index (CFI), where

$$\text{TLI} = \frac{\frac{T_0}{\text{df}_0} - \frac{T_1}{\text{df}_1}}{\frac{T_0}{\text{df}_0} - 1}, \quad [12]$$

$$\text{CFI} = \frac{(T_0 - \text{df}_0) - (T_1 - \text{df}_1)}{T_0 - \text{df}_0}. \quad [13]$$

Here, M_0 is more restrictive than M_1 , the baseline model. Of the two, CFI is normed to lie between 0 and 1, whereas TLI is approximately normed. Almost invariably, they are used to compare the fit of the fitted model against a model that assumes that variables are uncorrelated. When used in this fashion, TLI and CFI values are very large. When comparing a set of theoretically driven models, it may be more interesting to use as a baseline the simplest theoretically driven model under consideration rather than the substantively uninteresting independence model. When used in this fashion, these statistics express in some sort of percentage how much is gained by each of the models under consideration relative to the most parsimonious model. Note that when using the TLI and CFI indices, M_0 need not be a special case of M_1 .

Discussion

GOF assessment necessarily involves subjective judgment. Models are just approximations to real-life phenomena. Consequently, any model will be rejected if the sample size is sufficiently large. This should not be taken to imply that GOF testing is meaningless. Rather, it is our view that researchers should always assess the overall GOF of their models using a GOF statistic to assess the magnitude of the discrepancy between the data and the model taking into account sampling variability.

If the selected model fits well, researchers should then:

1. Assess the power of the statistic against meaningful deviations from the selected model, as it may well be that the statistic has no power to distinguish between the selected model and substantively meaningful alternative models.
2. Perform a piecewise assessment of the selected model to examine if, although the model fits well overall,

some parts of the data are not well captured by the model.

3. Consider whether models that cannot be distinguished empirically from the selected model (i.e., equivalent models—see MacCallum *et al.*, 1993), exist.

Researchers should always report substantively interesting models equivalent to their selected model when they are aware of them and argue their choice using substantive arguments, since by definition, a choice between two equivalent models can only be made on substantive, not on empirical grounds.

On the other hand, if the model does not fit well, researchers should:

1. Perform a piecewise assessment of the model attempting to determine the source of the misfit. This may be aided by modification indices (i.e., Lagrange multiplier tests), but see MacCallum *et al.* (1992).
2. Assess the magnitude of the discrepancy between the fitted and expected statistics. For covariance structure analysis, the SRMR provided may be used to examine the average magnitude of the discrepancy. In addition, the magnitude of each standardized discrepancy, that is,

$$\frac{s_{jk}}{\sqrt{s_{jj}\sqrt{s_{kk}}}} - \frac{\hat{\sigma}_{jk}}{\sqrt{\hat{\sigma}_{jj}\sqrt{\hat{\sigma}_{kk}}}}, \quad [14]$$

should be inspected.

In any case, when selecting a model among competing alternatives, they should strive for model parsimony. To this end, they may inspect GOF indices that penalize adding parameters by, such as the AIC or BIC indices to the model. Alternatively, they may compute the CFI index, using as a baseline, the most parsimonious substantively meaningful model considered.

Finally, when many variables are modeled, it is unrealistic to expect that any parsimonious model will fit well: the overall test statistics will be large, because some parts of the data will not be well reproduced by any parsimonious model. In this context, Browne and Cudeck's (1993) proposal of assessing whether a model fits the data closely, is an attractive alternative to assessing whether the model fits exactly. Consider the root mean square error of approximation (RMSEA) index,

$$\text{RMSEA} = \sqrt{\max\left(\frac{T - \text{df}}{N \times \text{df}}, 0\right)}. \quad [15]$$

Like other indices, the RMSEA penalizes models with too many parameters. Unlike the AIC or BIC criteria, the RSMEA is bounded below by 0. Furthermore, Browne and Cudeck derived its asymptotic distribution. Testing $H_0 : \text{RMSEA} = 0$ is equivalent to testing $H_0 : \boldsymbol{\sigma} = \boldsymbol{\sigma}(\boldsymbol{\theta})$. For large models, this null hypothesis of exact fit may be

too stringent, and Browne and Cudeck suggested testing instead, $H_0 : \text{RMSEA} \leq 0.05$. This is a test of close fit, where close is arbitrarily defined as $\text{RMSEA} \leq 0.05$. Moreover, model selection may be aided by inspecting the confidence intervals around their respective RMSEAs (Steiger, 2007).

Numerical Examples

Discrete Data

We fitted a two-parameter logistic model with a normally distributed latent trait to the Law school admission test (LSAT) 7 data. A thousand observations are available on five binary variables. The model was estimated by ML. **Table 1** gives some relevant GOF statistics. As these data are not sparse, the p -values for χ^2 and G^2 are accurate, and they are similar to that of the new test M_2 , which yields accurate p -values even for highly sparse data.

Using a 5%-significance level, χ^2 and G^2 suggest that the model be barely accepted, whereas M_2 suggests that the model be barely rejected. Statistics with a higher value to degrees-of-freedom ratio are generally more powerful, and the results of **Table 1** suggest that M_2 has higher power.

The cell residuals are not very helpful for piecewise assessment of fit. Significant residuals (at the 5% level) are obtained for patterns (10000), (01001), and (01000), which might suggest that the fit of the model could improve by dropping Item 2. The inspection of univariate and bivariate residuals offers a different picture. Significant residuals are obtained for (1,3), (1,5), (1,4), and (2,3), which suggest that the model misfits because of item 1. This is indeed the case as reflected in **Table 2**, where we provide Pearson's χ^2 statistics after dropping one item at a time.

Continuous Data

We model the responses of 438 US respondents to the five items of the satisfaction with life scale (SWLS). The items

Table 1 Goodness-of-fit (GOF) results for the LSAT 7 data

Stat	Value	df	p-value	Value/df
χ^2	32.48	21	0.05	1.55
G^2	31.70	21	0.06	1.51
M_2	11.94	5	0.04	2.39

Table 2 GOF results for the LSAT 7 data dropping one item at a time, 7 df

Item dropped	1	2	3	4	5
χ^2	5.01	9.52	8.59	18.68	9.86
p-value	0.66	0.22	0.22	0.01	0.20

Table 3 GOF results for the SWLS data

NT				ADF			
Stat	Value	df	p	Stat	Value	df	p
T	10.38	3	0.02	T_B	8.72	3	0.03
T_B	10.38	3	0.02	T_{YB}	8.55	3	0.04
				T_S	7.17	3	0.04
				T_a	6.90	2.89	0.07

are rating scales with seven response alternatives and will be treated as continuous. A two-factor model where “In most ways my life is close to my ideal,” “The conditions of my life are excellent,” and “I am satisfied with my life,” are taken as indicators of the factor satisfaction with present life, the and “I am satisfied with my life,” “So far I have gotten the important things I want in life,” and “If I could live my life over, I would change almost nothing,” are taken as indicators of the factor of satisfaction with past life. The factors are correlated. **Table 3** lists a number of GOF statistics obtained using the maximum-likelihood fitting function either under normality assumptions (NT) or under asymptotically distribution-free (ADF) assumptions.

Under NT, $T = N\hat{\chi}^2$, the minimum of the ML fit function multiplied by the sample size is provided, along with Browne's test (eqn [7], T_B). Under ADF assumptions, **Table 3** lists Browne's test, Yuan and Bentler's test (eqn [8], T_{YB}), and the Satorra-Bentler mean and mean and variance adjustments to T , T_S , and T_a , respectively. Notice that for T_a , the degrees of freedom are estimated as real numbers.

The model does not fit very well, and there is not much difference between the results under NT or ADF assumptions. All statistics yield similar p -values. Inspection of the z -scores for the residual covariances reveals significant residual covariances among items from different factors. The magnitude of the residuals is not large, however. The average standardized residual is $SRMSR = 0.015$, and the largest standardized residual is 0.04. It appears that the model yields a close enough fit. Indeed, the RMSEA (eqn. [15]) obtained is 0.056, and the p -value for testing whether the population RMSEA is smaller than 0.05, is 0.35.

Concluding Remarks

Our presentation has focused on models where the data can be summarized using some statistics (proportions, covariances, etc.). The fit of many interesting models cannot be assessed using summary statistics. For instance, the fit of a linear regression model cannot be assessed using covariances (i.e., within a SEM framework) because there are zero degrees of freedom. In the context of linear

regression and related models, R^2 is sometimes described as a GOF statistic. However, R^2 is actually a coefficient of determination, the proportion of the dependent variable that can be predicted from the independent variables. A linear regression model can fit the data perfectly, yet, R^2 will be zero if the slope is zero. Pure GOF statistics exist in regression and related models only in the presence of replicates (i.e., repeated observations for the same level of the predictors). In the general linear model, they are generally referred to as lack-of-fit tests. When no replicates exist, then, the observations must be grouped in some way to assess the GOF of the model. A typical example is the Hosmer–Lemeshow GOF statistic for logistic regression (see Hosmer and Lemeshow, 2000).

Clearly, GOF assessment has been more extensively developed in SEM than in other areas. New developments in GOF assessment for multivariate discrete data are strongly related to SEM procedures, and we expect further developments in GOF assessment procedures for multivariate discrete data along the lines of SEM developments. For instance, the notion of testing whether a model fits closely the data (as opposed to exactly), is yet to be brought into the multivariate discrete arena. More research is also needed on GOF assessment when the observed dependent variables are of mixed type (continuous and categorical). Finally, further research is needed on GOF-assessment procedures when data arises from complex sampling schemes, such as those found in multilevel modeling.

In closing, model fit (i.e., absolute GOF) is no guarantee of a model's usefulness. A model may reproduce the data at hand well and yet be useless for the purpose it was developed. On the other hand, a model may fit poorly and yet yield useful predictions. In this context, the fact that a model fits poorly simply means that in principle, a model could be found to reproduce the data better, whose predictions could be very different.

Graphical Models

R G Almond, ETS, Princeton, NJ, USA

Motivating Example

The idea of representing a complicated statistical model with a graph—a diagram in which icons are used to represent the variables and edges used to represent the relationship between variables—dates back to Wright's pioneering work on path analysis. In 1980, Darroch, Lauritzen, and Speed noted a class of models for contingency tables that had factorization structures and independence properties that could be described with an undirected graph. They called these models graphical models and noted several properties that made them both computationally convenient and readily interpretable. The following example illustrates some of the power of the method.

Table 1 presents the covariance matrix for the scores in five mathematics exams for 88 students. Zero covariances would indicate that scales represented by the five exams are independent. There is no evidence of independence, which is unsurprising as there is likely to be some kind of general mathematical ability factor that will produce correlation among the five scores.

A key insight of graphical models is that it is not the marginal independence of two variables (i.e., their correlation after averaging over the other variables), but their conditional independence (their correlation after conditioning on the other variables in the model) that is important. Dividing by the variance (the main diagonal) produces the correlation matrix. Inverting the correlation matrix and scaling the main diagonal entries to all be 1 produces **Table 2**. In this table, the values which are clearly nonzero have been shaded and the values close to zero are left unshaded. This reveals some conditional independence properties: for example, mechanics is independent of statistics given the other variables.

Figure 1 shows a graphical representation of the partial correlation matrix. In this graph, the nodes (drawn as rounded rectangles with a label) represent the variables in the model. Every place where there is a nonzero (shaded) entry in **Table 2**, there is an edge between the nodes. Note that algebra separates mechanics and vectors from analysis and statistics. This intuition is backed up with a conditional probability relationship that is present in the underlying distribution: mechanics and vectors are conditionally independent of analysis and statistics given algebra. This suggests several possible substantive interpretations, in particular, that algebra is at the intersection of the five different subareas within mathematics.

Graph Theory

A graph $G = \langle \nu, \varepsilon \rangle$ has two sets: the first set, ν , is a set of nodes or vertices (which usually correspond to variables in the model), and the second set, ε , consists of pairs of elements of ν called edges or arcs. Graphs can be either directed or undirected, depending on whether the edge (i, j) is considered to be an ordered or unordered pair. In the directed case, node i is called the parent and node j is called the child and the edge is depicted as an arrow from node i to node j . (The terms ancestor and descendent are also used with directed graphs as the obvious extensions of parent and child.) An undirected edge is equivalent to having both (i, j) and (j, i) as directed edges, and undirected edges are usually depicted as lines with no arrowheads. In either case, if the edge (i, j) is in the graph, then node i and node j are neighbors.

A graph can also be represented by an adjacency matrix: a matrix whose rows and columns correspond to the nodes of the graph and where the entry in cell (i, j) is 1 if node i and node j are neighbors, and zero otherwise. For example, **Table 2** (taking the nonzero elements to be one) is the adjacency matrix of the graph in **Figure 1**. Note that the adjacency matrix of an undirected graph must be symmetric (this is not an issue as the partial correlation matrix must also be symmetric).

A path is a sequence of nodes, X_1, X_2, \dots, X_K for which (X_k, X_{k+1}) is an edge in the graph; for a directed graph, this implies that the path follows the direction of the arrows. A path for which X_1 and X_K are the same is called a cycle, and a graph with no cycles is called acyclic; an acyclic undirected graph is also known as a tree. A set of nodes S separates two nodes X and Y if every path from X to Y or from Y to X passes through a member of S . As shown below, it is this notion of separation that gives graphical models their expressive power because it corresponds to conditional independence statements in the joint probability distribution.

A set of nodes which are all neighbors of each other is said to be complete. A maximal complete set of nodes is called a clique. In **Figure 1**, the set {mechanics, vectors} is complete, but not a clique, as it is contained by {mechanics, vectors, algebra}, which is a clique. An undirected graph can be represented by its set of cliques. For example, $[MeVeAl][AlAnSt]$ are the cliques of **Figure 1** (where each variable is represented by the first two letters of its name). As shown in the next section, the cliques of a

**Figure 1** Graphical models for five math test scores. Adapted from Whittaker (1990).

graph are important because they correspond to factors in the joint distribution.

Consider any cycle of length greater than three, say X_1 , X_2 , X_3 , and X_4 . An edge between two nonconsecutive nodes in the cycle (say X_2 and X_4) is called a chord. A graph that has no cycles of length greater than 3 without a chord is called triangulated. Triangulated graphs are important because they are particularly simple to work with computationally. For this reason, edges are often filled in to make a nontriangulated graph triangulated. Often, the cliques of the triangulated graph are arranged in a tree (in which the nodes correspond to sets of variables) is such a way that the subset of nodes in which each variable appears is a subtree of the overall structure. This transformation of the original graph is called a tree of cliques, or, if new nodes related to the intersection between variables are added, a junction tree. Generally, the computational complexity of working with a given graphical model is related to the size of the largest clique (after triangulation if necessary). This is called the tree-width. Choosing a fill-in that produces an optimal tree of cliques (i.e., one with the lowest treewidth) is a difficult problem; however, in many cases, simple search heuristics yield reasonable results.

Factorization and Conditional Independence

A graphical model is a joint probability distribution over a collection of variables that can be factored according to the cliques of an undirected graph. Let $\mathcal{G} = \langle \nu, \varepsilon \rangle$ be a graph whose nodes correspond to the variables in the model, and let C be the set of cliques in the graph. Let \mathbf{v} be an instantiation of the values in ν and let \mathbf{v}_C be the corresponding set of values for the variables in $C \subset \nu$. Then we can write the joint probability distribution as:

$$p(\mathbf{v}) = \prod_{C \in \mathcal{C}} \phi_C(\mathbf{v}_C) \quad [1]$$

In this equation, $p(\mathbf{v})$ should be interpreted as a probability mass function if all of the variables in ν are discrete, and a density function if any of the variables are continuous. The factors, $\phi_C(\cdot)$ are called potentials (sometimes Gibbs potentials; the term comes from statistical physics). The potentials can be probability distributions, conditional probability distributions, or products of any of the above. Generally, they are not interpreted directly and often they are left unnormalized.

The original use of the term graphical model was to distinguish a subset of the number of possible log-linear models for contingency tables that could be represented as a graph. Consider the set of possible models over three discrete variables A , B , and C . The models $[A][B][C]$, $[A][BC]$, $[AB][BC]$, and $[ABC]$ (and ones that are equivalent after relabeling the variables) are all graphical – the factors correspond to the cliques. The no-three-way interaction model $[AB][BC][CA]$ is not graphical because

the clique should be $[ABC]$ (the three factors do not correspond to cliques). Difference in the substantive interpretation of the no-three-way interaction model from the three-way interaction model is quite subtle; thus, restricting consideration to graphical models does not greatly limit the interpretability. Although the no-three-way interaction model has fewer parameters, it also is more difficult to work with, requiring iterative solutions to fit the model to data.

Restricting the variables to have a multivariate normal distribution creates a set of models corresponding to covariance selection models. (Note that for normally distributed data, the pairwise correlations define the joint distribution, so all models can be expressed with a graph, although it might be the saturated graph in which all nodes are connected.) In fact, there are three classes of graphical models for which most computations can be done exactly: (1) models in which all variables are discrete (graphical log-linear models), (2) multivariate normal distributions, and (3) finite mixtures of multivariate normal distributions. The graphical notation can be used to express other kinds of models, but operations on those kinds of models frequently involves integrals that must be solved numerically. (For example, the standard unidimensional item response theory model can be drawn as a graphical model with the observable outcome variables conditionally independent given the latent ability variable. However, the model is not a conditional Gaussian distribution; therefore estimating examinee ability using this model requires numeric integration.)

The Markov property of a graphical model states that if X and Y are variables in the graph, and S is a set that separates X from Y in the graph, then X is conditionally independent of Y given S , sometimes written $X \perp\!\!\!\perp Y | S$. This Markov property drives a number of efficient algorithms for computation, as well as aiding in the interpretation of the model. Probability distributions with this property are sometimes called Markov random fields.

Consider the well-known example of Simpson's paradox in which a university has several departments, each of which admits a different proportion of their applicants, and each of which has a different proportion of women in their applicant pool. Further assume that each department is completely gender neutral in their admissions decisions. The graph shown in **Figure 2** illustrates these assumptions. The nodes gender and acceptance are connected in the graph, so they are marginally dependent. Depending on whether women prefer more- or less-selective departments, the university will appear biased against or toward women. The graph tells the story visually:

Figure 2 A Graphical model illustrating Simpson's paradox.

it is the preference of women for more (or less) selective departments that causes the marginal dependency.

A fundamental result in the theory of graphical models is that factorization (according to a graph) implies the Markov property (with respect to that graph) and vice versa. This is sometimes known as the Gibbs–Markov equivalence theorem. Going from the factorization to the Markov property requires no special assumptions, but going from the conditional independence statements to the factorization requires that the probability for all configurations of the variables be positive. This can present a problem if there is a deterministic constraint between two or more variables; however, in practical circumstances, it can usually be made to work.

The Gibbs–Markov equivalence property has particular salience when building graphical models from expert opinion. The usual practice is to first elicit the conditional independence properties, then specify the probabilities for the factors defined by the cliques of the graph.

Related Graphical Representations

Although this article describes graphical models used in the narrow sense (models on an undirected graph), the term is often used to describe any model that is factored according to a graph. Two other classes of models, Bayesian networks and chain graph models, use directed or semidirected graphs to expand the expressive power of the graphical models. Path diagrams, while related in intent, have slightly different rules for interpretation.

A Bayesian network is a probability model defined over an acyclic directed graph. It is factored by using one conditional probability distribution for each variable in the model, whose distribution is given conditional on its parents in the graph. Variables which are separated in the graph are still independent, but the simple graph separation used for the undirected graph is replaced with the more complicated d -separation, which takes into account the effect of competing explanations for observed values.

A Bayesian network can be converted into an undirected graphical model by connecting all of the nodes that are involved in each factor. This requires that the parents of each node be joined or married. The process of joining parents is known as moralization and the undirected graph corresponding to a given Bayesian network is called a moral graph. Computing the moral graph is the first step of many computational algorithms for Bayesian networks.

Chain graphs use a mixture of directed and undirected graphical edges to describe independence relationships among the variables. A chain graph is divided into a series of blocks; within a block, all edges are undirected, and between blocks, the edges are directed. The blocks often correspond to stages in an experiment; for example, one

block could be measurements taken before the start of an educational intervention, and another measurements taken after. A third block could represent background variables about the students and schools. The directed edges flow in the temporal direction: from preintervention to postintervention measures and from background variables to either.

Path diagrams bear an obvious similarity to graphical models (especially the directed Bayesian networks) and, indeed, the work on path diagrams was an inspiration for the later work on graphical models. However, there are some subtle and important differences. Some are obvious: path diagrams include explicit nodes for error terms, while these are usually implicit in graphical models and Bayesian networks; and path diagrams allow some kinds of expressions (double-headed arrows and reciprocal relationships) that are not allowed in graphical models. Other differences are more subtle. In particular, the discipline of structural equation modeling concentrates on modeling the covariance matrix, while graphical models concentrate on modeling the inverse covariance matrix. The implication is that the conditional independence assumptions implicit in the structural equation model are not always clearly expressed; hence, the Markov property may not hold for the path diagram. Most path diagrams have an equivalent representation as a graphical model, but there are some exceptions (which typically are models that are difficult to estimate).

Model Fitting, Model Selection, and Analysis of Deviance

The parameters of Gaussian (normal), log-linear, and conditional Gaussian graphical models can be estimated through maximum likelihood estimation. The difficulty of this estimation procedure depends on the topology of the graph. If the graph is triangulated, then the parameters can be estimated separately for each clique. In Gaussian models, the key parameters are based on the covariance matrix of the variables in the clique. For the log-linear models, the model for the clique is just the saturated log-linear model, whose sufficient statistics are just the observed cell counts. Note that this procedure counts the variables in the intersections between the cliques twice; therefore, to avoid this double counting, then divides by the distribution over the variables in the intersection between the cliques. Thus, the final model looks like:

$$p(v) = \frac{\prod_{C \in \mathcal{C}} \phi_C(v_C)}{\prod_{I \in \mathcal{I}} \psi_I(v_I)} \quad [2]$$

where \mathcal{C} is the set of cliques of the graph, \mathcal{I} is the set of intersections; $\phi_C(v_C)$ is the marginal distribution over the

clique \mathcal{C} , and $\psi_I(v_I)$ is the marginal distribution over the intersection \mathcal{I} . This is a fundamental representation of graphical models that is used in many computation algorithms.

If the model graph is not triangulated, then iterative algorithms are required to estimate the model parameters. The most common estimation uses iterative proportional scaling. If prior distributions are specified for model parameters, it is possible to estimate the parameters using Markov chain Monte Carlo estimation.

Many common software packages can be used to fit graphical models to data. The key to specifying a graphical model is noting that the cliques of the graph are specified as multiway interactions using the Wilkinson and Rogers model specification notation, which is used by many common statistics packages such as SAS and S. Using the S `glm` function, the model in **Figure 2** would be written as `'Count ~ Gender*Department + Department*Acceptance'` and the saturated model would be written as `'Count ~ Gender*Department*Acceptance'`. Special graphical model software packages, such as MIM or CoCo, allow models to be specified in the clique notation.

It is usually possible to fit more than one model to a given data set. The saturated model (the one with all possible edges) should always fit, but there may be more parsimonious models that fit as well. A general measure of model fit for graphical models is the deviance which is defined to be twice the difference in log likelihood between the current model and the saturated model. This has an asymptotic χ^2 distribution, with degrees of freedom equal to the difference between the number of parameters in the candidate model and the number of parameters in the saturated model. For Gaussian models, the number of parameters is simply the number of edges. For discrete models, the number of parameters is the sum of the sizes of the cliques, where the size of the clique is defined as the product of the number of states of each of the variables. The size of the saturated model is thus exponential in the number of variables in the model.

Suppose that a researcher is comparing two different candidate models: model A and model B. If model B's graph can be produced from model A's graph by removing edges, model B is nested within Model A. The difference in their deviances is a likelihood ratio test comparing the two models (with the degrees of freedom given by the difference in the number of parameters). If there are a series of nested models (say by successively removing a series of edges), then these can be arranged in a table that is similar to an analysis of variance table. This is sometimes called the analysis of deviance.

Note when the data are sparse with respect to the number of variables (i.e., when there are a large number of empty cells in the contingency table, or because certain

combinations of variables are rare), then the parameter of the saturated model may be difficult to estimate and the sample deviance may have poor approximation to the χ^2 distribution. In such cases, the likelihood ratio test may work well even if the difference of the deviances is not a numerically stable way to compare models.

Stepwise procedures are frequently used to search for the best model. These can either start from the saturated model (all edges present) and proceed to remove edges, or from the complete independence model (no edges present) and proceed to add edges. In the case of log-linear models, model selection through adding or removing edges restricts the search to the class of graphical models; however, the difference in interpretation between the graphical and nongraphical models compatible with the same graph is fairly subtle, and often not relevant for interpreting the results in a wider scientific context. Note that such a stepwise procedure is not guaranteed to converge to the optimum (in the sense of best-fitting the observed data) model.

If the models do not nest, then the usual penalized likelihood measures (e.g., Akaike's information and Bayesian information) can be used to compare models. Searching the space of all possible models is an area of active research, and there are many algorithms proposed for this purpose (especially algorithms that search for directed and semidirected graphs). Most of the algorithms require all data to be at least partially observed (missing values are allowed), but some include latent variables in the search space.

Two cautions are worth making when considering the application of these model discovery algorithms. First, it is possible to over fit models to data, and hence it is important to use cross-validation to evaluate the model fit. Second, many of the model search techniques are motivated by attempts at causal discovery (generally, directed graphical models in which the edges are oriented in the causal direction will have fewer edges). However, the usual limitations of inferring causal relationships from observational data still apply. This is especially important if the work is to be presented to a lay audience that is not familiar with the definitions, assumptions, and limitations of the causality search procedures.

Summary

Graphical models are joint probability distributions that can be factored according to a graph. The key property of graphical models is that separation in the graph implies conditional independence of the variables. This conditional independence property allows computers to use the graphical structure to derive efficiency computation

algorithms. It also helps researchers visualize the properties of the joint distribution.

Growth Modeling

I Plewis, University of Manchester, Manchester, UK

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Growth curve – A graphical or algebraic representation of the change in a variable with age.

Hierarchical linear model – A statistical model for data measured at two or more levels that partitions and accounts for the variances and covariances at different levels, also known as a multilevel model.

Missing at random (MAR) – The condition wherein the data values that are missing depend only on the values that are observed and not, in addition, on the missing values themselves.

Multiple imputation – A method of adjusting for missing data that assumes that the data are missing at random and that takes account of all the information about missingness in the observed data.

Multivariate analysis of variance – A statistical model in which two or more response (or dependent) variables, usually assumed to follow a multivariate normal distribution, are related to one or more categorical explanatory variables.

Random effect – An effect that varies from unit to unit and where the interest is in the distribution (usually assumed to be normal) of this effect and, in particular, in its variance, rather than in the values for each unit.

Introduction

The growth of all animals is both systematic and variable. It is systematic in the sense that it is usually possible to model growth as a smooth function of age (or time) and variable in the sense that there are individual differences: not all members of a species grow at the same rate. Modeling growth is therefore a statistical as well as a biological problem, one that has interested statisticians for well over half a century. Much of the early impetus for the work in this area came from a desire to model weight growth in farm animals (e.g., Wishart, 1938) and height growth in children (e.g., Deming, 1957). Indeed, auxology – the science of human growth – has generated important advances in growth-curve modeling as discussed by, for example, Healy (1989). Like human biologists, since developmental psychologists too focus on changes with age, they also came to appreciate the potential of modeling

age changes in cognitive outcomes such as language development and processing speed. Some (e.g., Bayley, 1949) saw the development of mental abilities as being akin to growth in height. However, the application of growth curves to psychological variables did not proceed in an uninterrupted way. Concerns about measurement error and the comparability of measures over time led to moves away from age-related models – in other words, analyzing difference scores when there are just two repeated measures and fitting growth curves when there are more than two. Instead, conditional or regression models for change became more popular with the measure of a construct at baseline being used as an explanatory or control variable and interest then centering on the correlates of later measures for a fixed baseline. The paper by Cronbach and Furby (1970) was influential in this shift of emphasis, with the move back to growth curves initiated by Rogosa *et al.* (1982) and, particularly, by developments in statistical software which meant that flexible models of growth could be applied to the often messy data generated by longitudinal studies in the behavioral sciences.

Educational researchers also have much in common with developmental psychologists, not least because of their mutual interest in cognitive development and learning. Questions such as how quickly children learn to read and do mathematics, and how progress in subjects taught at school varies by, for example, gender and social class and also by school attended are important areas in educational research. In principle, the development or growth in a construct like mathematical ability can be modeled as a function of age. In practice, however, there are particular difficulties with measures of educational attainment because there are no educational tape measures; in other words, there are no fixed scales that apply across all ages. Instead, researchers use different and age-appropriate measures or tests for pupils at different stages of their school careers, but generating a single-objective scale that can be used across the age range is then problematic. Vertical equating has been used to try to get round this problem but with limited success and then only for rather narrow age ranges.

The absence of fixed scales for educational attainments renders the application of growth-curve models to educational data more difficult than it is to, say, height data but certainly not impossible. Although we are unlikely ever to be able to specify and estimate a single model for reading growth that represents underlying changes with age (e.g., rapid progress in the early years in school, reaching an

asymptote in late adolescence), we can attempt to answer an arguably more important set of questions about the correlates of growth. We can do this by constructing scales that make different assumptions about growth and then testing the sensitivity of estimates of correlates of growth to these different assumptions about scale. This issue is discussed in Plewis (1996), and we return to it in the context of our example. This article sets out growth-curve models for one and more than one attainment variable that is measured (on a continuous scale) on several occasions. First, however, as our example is woven into the development of the models, the study from which the data are taken is introduced.

The Example Data

In our example of an application of growth-curve models to educational attainments, data from the 1970 British Cohort Study (BCS70) are used. This study is the third of what is now a series of four UK birth cohort studies covering cohorts of children born in 1946, 1958, 1970, and 2000/2001. Data were collected from the full cohort on up to five occasions in BCS70 before the age of 21: at birth and then at 5, 10, 16, and 21 years. In addition, a subsample of these children was measured at 22 and 42 months. Consequently, we have longitudinal records (records from the same children) that span the period from early childhood (at 22 months when learning is just beginning) to early adulthood (at age 21 years by which time formal learning has usually ended). Although the initial cohort consisted of over 17 000 births, we restrict ourselves to the subsample of children measured at 22 months ($n = 2457$). We consider two measures of attainment that we call literacy and numeracy while recognizing that the distinction between them is not easily drawn at very young ages. We focus on the relative progress of boys and girls on these two outcomes.

Table 1 gives the number of observations and the observed age range at each measurement occasion. It shows that there was a range of ages at each occasion and also a considerable amount of missing data. The missing

data at occasion 2 are mainly due to item nonresponse, to attrition at occasions 3 and 4, and to a teachers' strike at occasion 5. The sample at age 21 was a 10% subsample of the original cohort, and this resulted in only a small overlap with the 22-month data.

Table 2 gives the pairwise Pearson correlations across occasions for the two underlying variables (with literacy below the diagonal and numeracy above it). These correlations tend to be higher for occasions four, five, and six although the two correlations for occasions five and six are based on rather small samples. For literacy, the correlations decline as the interval between occasions widens, but this decline is not so apparent for numeracy.

We require a scale that covers the age range. There are a number of possibilities but not the space in this article to consider all of them. The approach adopted here is to use z -transformations so that, based on the observed scores, the scale has a mean of zero and a standard deviation of one at each age. This has the advantage of simplicity but does not, of course, incorporate any notion of growth, either in the mean or, importantly, in the variance. We return to scaling issues below.

Growth-Curve Models

Educational researchers are interested in how attainment changes with age and, especially, to what extent there is variation between individuals in their growth or change parameters. In addition, they often want to explain this interindividual variation in terms of both fixed and time-varying characteristics of these individuals and, sometimes, the characteristics of groups to which the individuals are attached, for example, schools and neighborhoods. Moreover, researchers are often interested in analyzing more than just one measure of attainment and want to know how sets of variables change together with age.

A multilevel (ML) or hierarchical linear modeling (HLM) approach to the analysis of these kinds of questions has many advantages. We regard the repeated measures of the outcome as nested within the sampled individuals to form a two-level structure as illustrated for a hypothetical design in **Figure 1**. Each sampled case could be measured on all five occasions as individuals one and two in **Figure 1** were. Both were measured every year for 4 years but then with an interval of 2 years between occasions 4 and 5. They were not, however, both measured at precisely the same ages: for example, at occasion 2, individual one was exactly 1 year old, whereas individual two was age 1.2 years. Individual three is measured just 3 times, missing occasions 2 and 4, whereas individual four is lost from this hypothetical study after occasion two. The specification of the ML models can, as we shall see, be flexibly adapted to a variety of research questions and to a range of data sets. In particular, the models easily handle

Table 1 Sample size and age range by occasion: BCS70

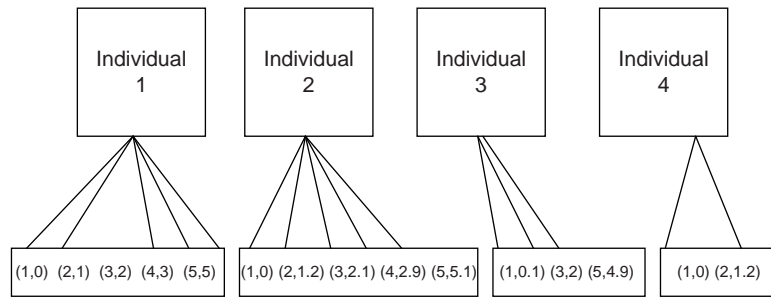

Occasion	Age range (years)	Observed sample sizes	
		Literacy	Numeracy
1	1.8–2.4	2412	2388
2	2.8–4.0	1317	1275
3	4.9–6.0	1636	1889
4	9.7–11.6	1744	1743
5	16.0–16.8	753	487
6	21 ^a	173	124

^aAge at test not collected.

Table 2 Pairwise correlations across occasions for literacy and numeracy and numbers of observations: BCS70^a

Occasion	Occasion					
	1	2	3	4	5	6
1		0.30 (1230)	0.22 (1841)	0.22 (1694)	0.13 (477)	0.20 (122)
2	0.26 (1298)		0.29 (1022)	0.44 (920)	0.43 (269)	0.17 (73)

**Figure 1** Hierarchical structure. Bottom boxes: (o,t) refers to occasion and age at measurement (in years).

the difficulties generated by (1) unevenly spaced measurement occasions (e.g., individuals one and two in **Figure 1**), (2) measurements missing for some occasions for all or some variables (individuals three and four), and (3) data collected across a range of ages within any one occasion (at occasion 1 for all four individuals). For many years, analysts used techniques based on multivariate analysis of variance (MANOVA) which could only handle regularly spaced and complete data, but these techniques are now redundant.

Linear Growth

Consider first, a simple model for linear (i.e., straight line) growth for a single continuous response (y) changing with age (a). We write:

$$y_{ij} = b_{0j} + b_{1j}a_{ij} + e_{ij} \quad [1]$$

Model [1] is a two-level regression model with occasions ($i=1..t_j$; level one) nested within individuals ($j=1..n$; level two) where, in **Figure 1**, $\max(t_j) = 5$ and $n = 4$. It is usual to measure age because deviations from its overall mean as the estimates from the model are more readily interpretable then. Here, we center age around 10 years. The model allows both the intercept (b_{0j}) and the growth rate (b_{1j}) to vary between individuals (j) and so we write:

$$b_{0j} = b_{00} + u_{0j} \quad [2]$$

and

$$b_{1j} = b_{10} + u_{1j} \quad [3]$$

where u_{0j} and u_{1j} are level-two random effects; they have zero means, a bivariate normal distribution, and are uncorrelated with the level-one residuals e_{ij} .

Models [2] and [3] are readily extended by including one (or more) explanatory variables z_j which vary across individuals (but not from age to age). In our case, this is gender with $z_j = 0$ for boys and 1 for girls so that we expect both mean differences between boys and girls (b_{01} : model [4]) and also differences in their growth rates (b_{11} : model (5)):

$$b_{0j} = b_{00} + b_{01}z_j + u_{0j} \quad [4]$$

$$b_{1j} = b_{10} + b_{11}z_j + u_{1j} \quad [5]$$

Substituting models [4] and [5] into model [1] gives us:

$$y_{ij} = b_{00} + b_{01}z_j + b_{10}a_{ij} + b_{11}a_{ij}z_j + u_{0j} + a_{ij}u_{1j} + e_{ij} \quad [6]$$

and the effect of gender on the slope or growth rate is represented by coefficient b_{11} for the cross-level interaction $a_{ij}z_j$. Model [6] (equivalent to models [1], [4], and [5] combined) can be fitted rather easily using a standard statistical package or with specialist ML software such as *MLwiN*.

As growth rates vary between individuals, the overall variance of the response y , conditional on (i.e., for fixed values of) the explanatory variables z , is a function of age.

This variance function is obtained from the last three terms – the random effects – in model [6]:

$$\text{var}(\mathcal{Y}_{ij}) = \sigma_{u0}^2 + a_{ij}^2 \sigma_{u1}^2 + 2a_{ij}\sigma_{u0,u1} + \sigma_e^2 \quad [7]$$

The term $\sigma_{u0,u1}$ in model [7] is the covariance between the intercept and the slope from which the corresponding correlation can be estimated. This correlation should, however, be interpreted with caution as it depends both on how age is centered and also on the underlying shape of the individual growth curves. We can extend the variance function in model [7] by allowing the within-person variance σ_e^2 to vary systematically with age rather than remain constant. We do this by allowing the effect of age to vary randomly at level one, replacing b_{1j} by b_{1ij} in model [1]. This enables us to deal with heteroscedasticity.

Nonlinear Growth

The model can be further extended to allow for changes with age that do not follow a straight line. Polynomial functions are flexible and commonly used:

$$\mathcal{Y}_{ij} = \sum_{q=0}^Q b_{qj} a_{ij}^q + e_{ij} \quad [8]$$

In model [8], Q is the order of the polynomial, determined from the data but with the restriction that Q is usually less and often much less than $\max(t_j)$. We now have $Q+1$ random variances and $Q(Q+1)/2$ covariances at level two.

The mean growth curve (i.e., the growth curve for the child that scores at the mean at each age) for our exemplar data from BCS70, measured on the selected (but arbitrary) scale of standardized scores at each age, is just a straight line through the origin with zero slope. Individuals' growth curves can, however, vary about this line as illustrated in **Figure 2**. Moreover, they can, in principle, be nonlinear even though the mean curve is a straight line. For example, some children might make particularly rapid progress in early childhood and then slow down, whereas others might start slowly and then have an adolescent growth spurt. We allow for possible nonlinearity by introducing a quadratic term in age (i.e., age squared) into the model for these data. Our main interest, however, is in the main effect of gender and the cross-level interactions of gender with age and age squared as these estimates of the fixed effects tell us how gender differences in the outcomes vary across the observed age range. **Table 3** gives the estimates, separately for literacy and numeracy, and **Figure 3** shows how gender differences vary by age for the two outcomes. The quadratic term dominates the gender differences for literacy and so girls are ahead of boys at very young ages and again in early adulthood but with only small differences during the

Figure 2 Individual growth curves.

Table 3 Gender estimates and standard errors: Main effect and age interactions from univariate models

<i>Fixed effects</i>	<i>Literacy</i>	<i>Numeracy</i>
Gender	*	0.10 (0.043)
Gender ^a age	*	-0.02 (0.005)
Gender ^a age ²	0.0029 (0.0007)	-0.0025 (0.0007)

^aEstimate less than its standard error.

period in school. The effect for numeracy shows girls slightly ahead of boys until they leave primary school (at age 11) but then falling behind.

Turning to the random effects shown in **Table 4**, we find that, for both outcomes, about 95% of the sample has linear growth rates that vary by about 0.10 units around the mean of zero and quadratic terms that vary by about 0.01 units around zero (rows 2 and 3 in **Table 4** give the variances and so we take the square root of these and multiply by ± 1.96). We also find that the within-person (or level-one) variance is not constant; instead it declines with age (because the covariance in line 9 of **Table 4** is negative), whereas the between-person (or level-two) variance increases with age. We must, however, interpret these changes in variance with age cautiously because the scales are constructed in such a way that the overall variance is constant.

Whenever we fit a statistical model to data, we must pay heed to the assumptions of the model. We can do this by (1) examining the distributions of the estimated residuals at each level (are they approximately normal?), (2) plotting intercept residuals against slope residuals to check for any outliers, and (3) plotting residuals against predicted values from the model and against the explanatory variables to check that, for instance, the assumption of roughly constant residual variance is reasonable.

Figure 3 Gender differences by age: literacy and numeracy.

Table 4 Estimates and standard errors: Random effects from univariate models

Random effects	Literacy	Numeracy
L2: Intercept var.	0.63 (0.034)	0.58 (0.034)

L2: Age ² var.	0.000022 (0.0000080)	0.000010 (0.0000070)
L2: Intercept, age cov.	0.021 (0.0023)	0.024 (0.0025)
L2: Intercept, age ² cov.	-0.0030 (0.00044)	-0.0021 (0.00043)
L2: Age, age ² cov.	-0.000050 (0.000033)	-0.00010 (0.000032)
L1: Intercept var.	0.39 (0.021)	0.44 (0.022)
L1: Age var.	0.0019 (0.00066)	0.0011 (0.00068)
L1: Intercept, age cov.	-0.016 (0.0017)	-0.017 (0.0018)

L – level; var. – variance; cov. – covariance.

Introducing a Higher Level

If we are fortunate enough to be able to analyze a study designed in such a way that the repeatedly measured individuals are located in a sample of schools, then we can answer questions about differences between schools in growth rates. For simplicity, we assume that a straight line model for growth is adequate and we remain interested in gender differences. Model [1] is now written as:

$$y_{ijk} = b_{0jk} + b_{1jk}a_{ijk} + e_{ijk} \quad [9]$$

Model [9] is a three-level model with occasions ($i=1..t_{jk}$) nested within individuals ($j=1..n_k$) now nested within the third level, schools ($k=1..K$). If we allow each intercept, growth rate, gender difference, and gender difference in growth rates to vary from school to school then model [6], the random part especially, becomes more complex:

$$y_{ijk} = b_{000} + b_{010}z_{jk} + b_{100}a_{ijk} + b_{111}a_{ijk}z_{jk} + v_{00k} + z_{jk}v_{01k} + a_{ijk}v_{10k} + a_{ijk}z_{jk}v_{11k} + u_{0jk} + a_{ijk}u_{1jk} + e_{ijk} \quad [10]$$

There are four random effects at the school level in model [10]: the overall intercept (v_{00k}), the growth rate (v_{10k}), the gender difference (v_{01k}) and the difference between boys' and girls' growth rates (v_{11k}). These random effects generate four variances and six covariances at the school level to add to the two variances and one covariance at the individual level and one variance at the occasion level. We might be able to explain some of the variation at the school level if we have measures – the pupil–teacher ratio, for example – at the school level.

Multivariate Growth-Curve Models

Rather than estimating two separate models, we might exploit the fact that literacy and numeracy are related at each age (the Pearson correlations vary from 0.30 to 0.81) to obtain more efficient estimates from a bivariate model. In addition, we can learn more about how the growth parameters covary. As Plewis (2005) shows, the general multivariate growth curve model (ignoring the school level for simplicity) can be written as:

$$y_{bij} = \sum_{q=0}^{Q_b} b_{bjq}a_{ij}^q + e_{bij} \quad [11]$$

Model [11] is the same as model [8] except for the addition of a third subscript, b ($b=1..H$). Here, H is the number of response variables (two in the example) and we have a three-level model. There is no level-one variation now because level one exists solely to define the multivariate structure. Variation between occasions within individuals is at level two and variation between individuals at level three. Note that Q can vary with b . Not only

does the variance of each response vary with age as in model [7], but the covariances between the responses do as well.

This model will provide us with:

1. Patterns of change that can vary across variables both in terms of their relation with age and with the correlates of growth, z_j
2. Correlations between growth parameters – the b_{bjj} – both within and between variables.
3. Model-based variances, covariances, and correlations at the individual level (level three), both within and between variables.

In fact, in our example, the fixed effects of interest (shown in **Table 5**) are little altered from those of the univariate models. The estimated correlation between the linear growth rates for literacy and numeracy is 0.66 suggesting that individuals' attainments grow at similar rates.

Concluding Remarks

We have seen how to specify and apply growth-curve models to educational attainment data, and our example has illustrated some of the strengths of this approach. First, all the available data on literacy and numeracy have been used, and this has been especially important in the presence of so much missing data: a complete case analysis would have been based on just 22 cases for literacy and 14 cases for numeracy. Second, we have been able to take account of variability in age at measurement within occasion and to handle unequal intervals between occasions because the models use these two measures in different ways: occasion defines a level but age defines one of the explanatory variables. Third, we have been able to show how gender effects vary across the age range. Finally, we have gleaned some extra information by analyzing literacy and numeracy together in a bivariate model.

We can extend the models in a number of ways. Rather than using polynomials to model change with age, we could, for example, use other functions of age (log, reciprocal, etc.) or we could model growth for a series of stages (e.g., before school, primary school, high school) by using different linear models for different stages, known as piecewise linear models or spline functions. We could

also expand the number of explanatory variables. Moreover, we could also use our estimated growth curve to make predictions about adult status, for example, level of educational qualifications, to test whether mean attainment or growth in attainment is a better predictor of later qualifications.

Educational researchers wishing to use growth curve models to learn more about the development of educational inequalities with attainment data should, however, proceed with caution. Plewis (1996) shows that group differences can vary according to the scale chosen. A full analysis of these data requires sensitivity analyses to determine whether and to what extent the conclusions are affected by changes in the age function used to model growth, by changes in the way the outcome measures are constructed at each age, and by varying assumptions about the scale of the underlying or latent variable with age. We might, for example, have generated a literacy age scale with means increasing with age and also allowing variance to increase with age just as height variance does.

The focus in this article has been on continuous outcomes. Sometimes, however, attainments are measured as binary outcomes – whether or not someone has achieved a particular proficiency level – sometimes as counts and sometimes as ordered categories. The latter situation currently holds in England where pupils are assessed in the core subjects of English, mathematics, and science at ages 7, 11, 14, and 16 and allocated to one of a limited number of levels at each age. It is possible to model binary and categorical outcomes as functions of age although the nonlinear nature of the models (logits, probits, etc.) can lead to problems in estimation. Plewis (2005) jointly models three measures of children's behavior using ordered logits.

A rather different approach to modeling proficiency is to model variation in the time taken to reach the required level. This is a survival model rather than a growth-curve model but can be formulated in an ML framework. There are also other ways of modeling change in attainment. For example, as mentioned in the historical background in the introduction, it is often useful to look at the correlates of educational progress: to what extent are variables related to the outcome at occasion t conditional on (or controlling for) earlier or baseline measures. In addition, we might want to relate change or growth in attainment to other time- or age-varying explanatory variables: for example, modeling change in attainment as a function of change in family economic circumstances. These models are widely used in econometrics and examples of both conditional models and models using a time-varying explanatory variable are compared with growth curves in Plewis (2001).

This article has adopted what might be termed a conventional ML or hierarchical modeling approach to growth. A somewhat different way of thinking about these issues has been provided by, for example, Muthén (1997), placing them in a structural-equations modeling framework where

Table 5 Gender estimates and standard errors: Main effect and age interactions from bivariate model

Fixed effects	Literacy	Numeracy
Gender	*	0.082 (0.043)
Gender ^a age	*	−0.02 (0.005)
Gender ^a age ²	0.0027 (0.0007)	−0.0019 (0.0007)

^aEstimate less than its standard error.

the growth parameters (intercepts, slopes, etc.) are regarded as latent variables. This idea has led to a further useful extension: latent class growth analysis where individuals are assumed to belong to a set of underlying or latent classes that reflect different patterns of growth. These classes are derived from the data in such a way that they take account of much of the variability in the growth parameters. This idea has been extended by Muthén (2004) into what he calls general growth mixture modeling which allows for variability between individuals within the latent classes. The software package Mplus can be used to fit these models. These developments have found particular favor in analyses of deviant and delinquent behavior in psychology and criminology where there are both empirical and theoretical grounds for supposing that there are just a small number of classes, each exhibiting a different pattern of growth. There have been fewer applications to educational attainment data where it is perhaps less obvious what the latent classes would be although Muthén (2004) does give an example in terms of engaged and disengaged high school pupils.

A feature of nearly all longitudinal observational studies, and particularly of our example, is the way the observed sample diverges from the target sample over time. Although we have seen how growth-curve models can incorporate all the observed data on the responses, we do have to assume that the data that are missing are missing at random. In other words, providing missingness at occasion t depends only on what has been observed at occasions $t-k$ ($k > 0$) and not on change from $t-1$ to t ; then our estimates are unbiased and efficient. We do, however, lose cases where there are missing data on the explanatory variables unless we use some form of adjustment such as inverse probability weighting or multiple imputation.

To sum up, growth-curve models, applied thoughtfully to longitudinal data, offer educational researchers opportunities for further insights into, for example, learning and into the development of educational inequalities.

Hierarchical Linear Models

D Rindskopf, CUNY Graduate Center, New York, NY, USA

© 2010 Elsevier Ltd. All rights reserved.

In many educational contexts, data occur in a nested structure. For example, we may measure the achievement level of a child in a particular subject matter. That child is located (nested) within a particular class of students, and we might expect that the child's performance would have been different had she been in a different class of students. Further, the child's class may be one of many within a particular school, and that school may be one of many within a school system, which is located within a larger educational or political unit (e.g., county, state, and region). Each level of the structure may have its own characteristics that influence the achievement of the child. Hierarchical linear models (and more general models, to be discussed later) are designed to properly model influences on outcome variables at all levels of such a hierarchy, including the proper handling of data dependencies created by the nested structure.

In this article, we describe a variety of models that are designed to accommodate a nested data structure. Some models are linear, but others are nonlinear; some involve nesting of people within higher level units (such as classes), while other models are applicable to repeated measures that are nested within individuals (including longitudinal studies). We begin with a very simple example, and then show how the principles involved can be used to expand the scope and type of models that may be used. These principles are all expansions or generalizations of those used in ordinary least squares (OLS) regression; often, the models can be viewed as a series of regressions for different levels of the data structure. Those unfamiliar with regression should read the article on univariate linear regression in this volume before reading the rest of this one.

Although we will not discuss it in detail, these methods also resolve the problem known as aggregation bias. It has been well known that correlations among variables at a higher level (e.g., measures on states) do not equal (and may be opposite in sign to) correlations among variables at the individual level. (A related problem that arises in categorical data analysis is known as Simpson's paradox.) Multilevel models are constructed so that inferences can be made at the right level, whichever level that happens to be for the problem at hand.

We discuss two examples of multilevel models. The first example is for a situation in which students are nested within colleges, and we wish to predict academic performance from one student-level and one college-level variable. The second example considers longitudinal data,

where a series of observations is made on each person over a period of time. Here, the nesting is of a different sort: Observations (over time) are nested within individuals.

Example 1: Two Levels, One Predictor at Each Level, Linear Model

For a first example, assume that the administration in 10 colleges in a particular country wants to see how well scores on an academic-achievement test given to all students in the last year of secondary school predict performance of students in their first year of college. If we consider each college separately, we may imagine that within each college, researchers fit a regression model to the data; the equation for school j would then be:

$$Y_{ij} = \beta_{0j} + \beta_{1j}X_{ij} + r_{ij}$$

In this equation, Y represents the grade of a student after the first year of college, X represents the score of the student on the secondary school-achievement test, i is used to refer to a specific student, and j to refer to a specific school. The coefficients are as in a linear regression model, except that each school has its own intercept (β_{0j}) and slope (β_{1j}).

As we shall be examining the intercept and slope of each school, and modeling them, it is important to be sure that these are quantities of interest. For the slope, there is ordinarily no issue (except perhaps multiplication or division by a constant in order to make a one-unit change more easily interpreted). In order to make the intercept meaningful, we will often have to transform X . One common strategy is centering, which means to create a new variable by subtracting the mean of X from each observed value of X . (For this article, we assume that the mean is computed for the whole data set, not for each college individually; this is called grand mean centering.) In any regression, the intercept represents the predicted value of Y when all predictors have a value of 0; therefore centering X will cause the intercept in each college's regression equation to equal the predicted value of Y for a student who is average on X (based on students from all included colleges). Using the exact sample mean is not necessary; sometimes, it is more important to use a round number for ease of interpretation. For example, if the mean is 497, it might be easier to subtract 500. Or, if a score of 600 is typically required for admissions, one might subtract 600 from all X values instead.

In addition to subtracting some value from X , one might also want to control the scaling further. In the United States, for example, where scholastic aptitude test (SAT) scores have a mean near 500 and a standard deviation near 100, one might divide by 100 so that a one-unit change in the transformed variable is more meaningful than a one-unit change on the original scale. This makes the slope more easily interpreted (and sometimes improves numerical stability.) From this point on, we will assume that X has been suitably scaled.

The term r_{ij} is a residual, indicating that the students' scores on the secondary school test will typically not predict their grades in college perfectly. The variance of the residuals in each college can differ among schools, but often modeling is begun by assuming that it is the same in each; we will denote the within-school residual variance by σ^2 , in which we do not use a subscript for college (j).

The intercepts and slopes will vary from college to college; some of this variation is just sampling variability due to using a sample of students within each college, but the other variability is due to true differences among colleges. The true variability in intercepts will be denoted by τ_{00} , and the true variability in slopes will be denoted by τ_{11} . (There is also a covariance between the intercepts and slopes, denoted τ_{01} , but this is seldom of much interest.)

If τ_{00} and τ_{11} are small, then the intercepts and slopes do not vary much among colleges, and one prediction equation will work equally well in each. The colleges will gain by knowing this, because now their prediction equation is known with greater precision due to the contribution of information from other colleges. Of course, unless the colleges are very similar, it is unlikely that both τ_{00} and τ_{11} will be small, which leads to a consideration of two issues: First, can we explain, based on characteristics of the colleges, why some have larger and others smaller intercepts and/or slopes? Second, even though the colleges differ, can we still use information from other colleges to help improve prediction in each college?

We may believe that characteristics of the colleges will have some relationship to either the intercept or the slope of their prediction equations. For example, it may be that schools differ in the difficulty of their courses, or in their grading standards. These may affect the intercepts or slopes. One might use the college's average value on X as a proxy for selectivity or difficulty; this could be a predictor for intercepts and/or slopes. Another possible measure would be the selection ratio, that is, the proportion of applicants who are admitted to the college.

We will now write the model for variability among colleges out more formally. The equations, which will first be presented without predictors, are:

$$\beta_{0j} = \gamma_{00} + u_{0j}$$

$$\beta_{1j} = \gamma_{10} + u_{1j}$$

The first equation says that the intercept in a particular college (j) is equal to some overall average plus a deviation of that college's intercept from the overall average. The second equation expresses the same idea for the slopes from each college. The variances of the residuals (u_{0j} in the first equation and u_{1j} in the second) are the values τ_{00} and τ_{11} mentioned previously. In this instance, they are called unconditional residual variances, because they are not conditioned (dependent) on any college-level predictors. When we analyze the data we will obtain estimates of both the mean intercept and slope (called fixed effects in most software) and the variances of the residuals (called random effects in most software).

Now suppose that the residual variances are large enough that we believe it worthwhile to try to account for some of their variation by using a college-level variable such as proportion of applicants admitted. In realistic applicants, there are often many potential variables, and variables that help predict differences in intercepts may not be the same variables that help predict differences in slopes. In this simple introduction, however, we will use only one such variable, which we will call W ; individual values of W are denoted W_j , with the subscript j indicating that the value of W will vary across colleges.

The extended model at the college level will now consist of the following equations:

$$\beta_{0j} = \gamma_{00} + \gamma_{01}W_j + u_{0j}$$

$$\beta_{1j} = \gamma_{10} + \gamma_{11}W_j + u_{1j}$$

The variances τ_{00} and τ_{11} of the residual terms u_{0j} and u_{1j} now represent conditional variances; that is, the variances remaining after accounting for variation in intercepts and slopes using information provided by the predictor W . These variances should now be smaller than in the unconditional model if W proves to be a good predictor, and measures analogous to R -square in the usual regression context may be calculated.

Multilevel models are very much like ordinary regression models in many ways: the outcome variable may be continuous or categorical. If continuous, it may be normally distributed or have some other distribution (e.g., exponential for survival models). If the dependent variable is categorical, models similar to logistic regression (for binary outcomes) or its extensions to polytomous or ordinal outcomes are possible. The right-hand side of any of the equations may require polynomial coding (e.g., the square and cube) for continuous predictors, dummy variables (or other coding methods) for categorical predictors, and product terms for interactions. The model may be intrinsically nonlinear, so that more complex models must be fit. All of these are possible, but outside the scope of this introductory article.

Example 2: Repeated Measures and Longitudinal Data

In many educational applications, people are measured more than one time. In some cases, these measurements extend over a long period of time; measurements may be daily, weekly, monthly, or yearly, for example. In other cases, the time sequence is not of great importance; for example, most models for test scores do not take into account that some items are administered before others. In either case, we can use the concept of nesting to reconceptualize the model for this type of data: we view observations as being nested within an individual. (In some instances, it might seem more natural to view time of observation as crossed with individuals, but this viewpoint is not usually considered in the multilevel literature, because doing so would reduce the utility of the model in many common situations, as we hope will become apparent shortly.)

As an example, suppose that a researcher wants to examine the growth of children's ability to sight-read words. Each month during the school year, she has every child in a class attempt to read a list of 20 words, and counts the number of words that the child can correctly read. We will treat the number of words read as if it were a continuous outcome variable to simplify the discussion in this section, and will later deal with the complexities that this type of outcome necessitates. The researcher wants to model the number of words read by each child as a function of the number of months into the school year. The time variable may be coded in a number of ways; one might be to start the variable Months at 0 for the first measurement period, and increase by one for each month. Another approach would be to use 0 for the last period of measurement, and number preceding periods as -1 , -2 , etc. Each possible choice determines the meaning of the intercept in the model. Again, for simplicity we will use a linear model, but realize that a straight line is unlikely to be a perfect description of such growth; we write the equation for each student as follows:

$$Y_{ij} = \pi_{0j} + \pi_{1j}M_{ij} + e_{ij}$$

where the subscript j is used to represent the individual student, i is used to represent a measurement occasion, Y_{ij} is the number of words read correctly by student j at occasion i , M_{ij} is the number of months (on whatever scale is chosen; here we will assume 0 is used for the first time of measurement) for measurement of student j at occasion i , and e_{ij} is the residual. The intercept π_{0j} and slope π_{1j} are different for each student, and again we will allow these to be predicted by variables at the higher level, which in this case is the individual student. For example, boys and girls may start at different levels, and they may progress at different rates. We may represent this by the following level-2 equations, in which F is equal to one for females and zero for males:

$$\pi_{0j} = \beta_{00} + \beta_{01}F_j + r_{0j}$$

$$\pi_{1j} = \beta_{10} + \beta_{11}F_j + r_{1j}$$

Of course the structure of all of these equations is exactly the same as the case in the first example where students were nested within colleges; only the context has changed. In these equations, the intercepts β_{00} and β_{10} represent the beginning number of words read (π_0) and the rate of change in words per month (π_1) for an average male (i.e., $F = 0$) in the study. The slopes in these equations, β_{01} and β_{11} , represent the difference in beginning number of words read and rate of change for females as compared to males. Again, the choice of coding makes a difference; gender could be coded in other ways, which would change the interpretation of each of the coefficients in these equations. The residual terms represent the amount by which the true values of π_{0j} and π_{1j} differ from that predicted for the average male or female.

This method of representing the model has several advantages over other methods. Most importantly, from a conceptual point of view, this is a model for each individual's growth pattern and for deviations of individuals from the average pattern. The focus is on the individual, rather than a group. As a consequence of this focus, in principle (and at present, in practice also) missing data are not a problem, as long as the cause for missingness is not related to the outcome variable. Each child could have a different pattern of months during which he or she was measured, and in fact the times of measurement do not even have to follow a common pattern. A child could be measured at months 1.25, 3.75, and so on, rather than exactly at the beginning of each month – the model remains the same. (Of course, in practice one must measure each individual a reasonable number of times, and with those times spaced in a reasonable way, in order to have accurate estimates of that child's growth pattern, but this is another matter.)

Generalized Linear and Nonlinear Models

Two general categories of complications frequently arise with multilevel models. As mentioned previously, not all dependent variables are continuous, and not all continuous variables have a normal distribution. In addition, not all relationships are linear, so nonlinear models must sometimes be considered. This section briefly describes some approaches to each issue.

In the second extended example described, the outcome was the number of words read correctly from a list of 20 words presented to the student. Equivalently, one might calculate the percentage or proportion of the list that was read correctly. If proportions were not extreme (e.g., if most were between 0.2 and 0.8), then using these in a model with a normal distribution might be a good

approximation to the correct analysis. A more accurate approach would be to consider each word as a trial, and the number correct as coming from a binomial distribution with an underlying probability of success for each trial that is constant across words. (An even more accurate model would allow words to have varying difficulties, and possibly to differ in other ways also, as in item-response theory. Often the simplifying assumption of equal difficulty is a good enough approximation to work well in practice.)

The binomial model is closely related to a more widely known model, logistic regression. For these models, the outcome that is modeled is usually the logarithm of the odds of a correct response, commonly called the logit of the probability of a correct response. The right-hand side of the level-1 equation for individual responding still has a linear form in these models; the left-hand side is the transformed value $\ln(\omega/(1-\omega))$, also denoted $\text{logit}(\omega)$ in some sources, where ω is the probability of a student responding correctly. The model for each individual is written in the following form:

$$\ln\left(\frac{\omega_{ij}}{1-\omega_{ij}}\right) = \pi_{0j} + \pi_{1j}M_{ij}$$

where ω_{ij} is the expected (not observed) probability of person j answering correctly during month i . The residual is not explicitly listed in this equation; instead, we state that $Y_{ij} \sim \text{Binomial}(20, \omega_{ij})$; that is, the observed number of words correctly read has a binomial distribution based on 20 trials, with probability ω_{ij} of being correct on each trial.

This is an example of a generalized linear model; these are extensions of linear models that include a linear model, a transform of the dependent variable, and a distributional form that is more general than a normal distribution. In this case, the logit is the transformation and the binomial is the distributional form.

Another example requiring the use of generalized linear models is when the outcome is a count, but the count is not the number of successes in a fixed number of trials, or it is a generally small count out of a very large number of fixed trials (in which case we are using an approximation to the binomial distribution). A researcher might count the number of times a student shows an aggressive behavior toward classmates, or the number of times the student raises his or her hand for the attention of the teacher rather than responding without being called on. If the period of observation is the same for each student and time of observation, then generally the Poisson distribution provides the simplest probability model for counts. A slight extension is required when the time of observation varies, so that the model is for the rate of behavior per period of time (number of hand raises per hour, e.g., when the time of observation may vary between 5 and 20 min). If F represents the expected number of acts and Z represents the amount of time for an observational period,

so that F/Z is a rate per unit time, the level-1 equation can be written in the following form:

$$\ln\left(\frac{F_{ij}}{Z_{ij}}\right) = \pi_{0j} + \pi_{1j}M_{ij}$$

As with the binomial model, there is no explicit error term in the equation because the count variable in the equation is an expected rather than observed frequency, and in this case it has a Poisson distribution.

A related model with the same form is the discrete-time survival model, in which we model the influences on the occurrence of an event. In education, we might wish to determine factors affecting whether, if so when, a student in college will drop out. Modeling whether or not the student drops out involves an ordinary logistic regression (or possibly with students nested within colleges if we observe many colleges). But to model the length of time to dropout is slightly more complicated. We observe each student over a series of semesters, and note whether he or she has dropped out or is still enrolled for that semester. The main aspects of this situation that are different from others with a binary outcome in each time period are that (1) drop out can only occur during one period, and (2) the sequence of observations can be stopped (censored) due to graduation so that the event we are looking for (dropout) may not be observed for that individual. It may not be obvious, but information from students who never drop out is nonetheless useful. Survival models developed in somewhat parallel ways in three areas: medicine (for obvious reasons), engineering (where they are generally known as failure time models), and sociology (where they are known as event history models).

Shrinkage Estimates

In many educational situations (in particular, test administration), one main objective is to estimate the ability (or some other characteristic) of individuals. The most obvious estimate when one merely calculates the total number of items right (or totals points for various nondichotomous items) is to use that total as an estimate. But if the quantity of information available for different individuals is not the same, this obvious estimate has statistical flaws. To take an extreme example, if one individual was administered two items (randomly sampled from an item pool) and got both right, while another was administered a hundred items and got 90 correct, would ability estimates of 1.00 and 0.90 (or monotonic transformations of these) seem reasonable? Would you be willing to believe that the first person has a higher ability than the second, even though he or she answered only two items? If not, what would a reasonable procedure be? It turns out that a reasonable procedure is to shrink all estimates to the mean (much like the phenomenon of regression to

the mean). The more information you have (e.g., the more test items), the less shrinkage there would be for that individual. Hierarchical models provide a general framework within which one can calculate differential shrinkage for individuals depending not only on the amount of information about the individual provided by the statistic of interest (standard error of the estimate), but also other (auxiliary but informative) data (e.g., the amount of training the individual has received in the subject matter). Hierarchical models can also be used to obtain improved estimates of units other than people (classes, schools, or higher level units).

Meta-Analysis

A situation in which it is not obvious that multilevel models can be applied is meta-analysis. In meta-analysis, a large number of studies about a topic are summarized by a measure of effect size, and by other characteristics of the study (age of subjects, whether a randomized design was used, etc.). The objective is to determine what the average effect size is, whether it varies (beyond sampling variability) from study to study, and if so whether study characteristics can be used to predict that variability. If we view subjects as nested within studies, it is easy to see that this falls into the realm of multilevel models, but with the individual level data missing (i.e., we only see summary statistics for the study as a whole). Most programs for multilevel models (and some additional specialized programs) can perform such analyses.

Recommended Reading

Several excellent textbooks are available to learn more about multilevel models. Raudenbush and Bryk (2002), whose notation is used here, and Goldstein (2003) cover a wide range of material on these models. Each of these also is associated with software to fit these models, HLM (Raudenbush *et al.*, 2004) for the former and MLWin (Rasbash *et al.*, 2005) for the latter. Other introductory books include Hox (1995, 2002) and Snijders and Bosker (2000). Gelman and Hill (2007) have a unique viewpoint, and many interesting approaches not found elsewhere. Other references in the reading list include more advanced works, as well as specialized references on various aspects of multilevel models.

Summary and Conclusion

When units are nested within higher level units, multilevel modeling should be used for three major reasons: (1) it is the correct analysis (which ordinarily would be a

sufficient reason), (2) viewing the model in this way leads to insights that are otherwise elusive about relationships, and (3) we avoid certain perplexing problems, such as aggregation bias. (Note that not all nesting produces a multilevel model; only when both levels are random effects is this true. For example, people nested within treatments, as in a typical ANOVA, do not result in the type of model discussed here because levels of treatment are typically fixed in number and are not a random sample from a population of treatments.) Multilevel models can be used not only in obvious situations such as when we have children in classes (and or schools), but also where subjects are nested within studies (meta-analysis), or where observations are nested within people (repeated measures and longitudinal studies). Using these models enables us to estimate effects within each level of a study, as well as between levels. Specialized software is readily available, and several major statistical packages now include the capability to fit multilevel models.

Hypothesis Testing and Confidence Intervals

T R Konold and X Fan, University of Virginia, Charlottesville, VA, USA

© 2010 Elsevier Ltd. All rights reserved.

Hypothesis testing involves estimating the probability (p) of observing a sample statistic (e.g., sample mean) that is equal to or more extreme than what is obtained from a sample, assuming that the sample is drawn from a population with a hypothesized population parameter value (e.g., population mean, μ). This article provides an overview of hypothesis testing through both point and interval estimation approaches. Although we use a population mean in some examples, the general principles discussed here extend to situations involving other sample statistics (multiple sample means, variance, proportion, correlation coefficient, etc.). Sampling distribution, sampling error, point estimate, interval estimate, statistical errors, and statistical power are among the topics discussed below.

Research Questions and Hypotheses

Research questions and hypotheses are usually based on a researcher's educated guess or intuition grounded in a good understanding of the phenomenon of interest. For example, a teacher might ponder whether a new instructional approach has an effect on student achievement as measured on a state-wide assessment of learning (the research question). Based on his/her pedagogical content knowledge, the teacher may generate a research hypothesis that this new instructional approach does impact student achievement. Although this research hypothesis does not indicate the direction of influence, such qualifications can easily be incorporated to reflect whether the researcher believes that this instructional approach will increase or decrease measured achievement. In general, a research hypothesis reflects a researcher's predictions and it directly shapes the statistical hypotheses to be empirically evaluated.

Statistical Hypothesis

Null Hypothesis

In order to test a research hypothesis, it is necessary to translate it into a statistical hypothesis. A statistical hypothesis is a numerical statement regarding a hypothesized population parameter. For example, knowing that the average state-wide assessment score for the general student population is 72 raw score points, a researcher might state the null hypothesis (H_0) as

$$H_0: \mu = 72$$

The H_0 is often stated to reflect the general state of affairs, or the condition of no difference. In hypothesis testing, assuming that the null hypothesis is true, we evaluate the probability of observing a sample statistic (e.g., sample mean) equal to or more extreme than what was obtained from our sample drawn from the hypothesized population with the population value (population parameter) stated in the H_0 (i.e., $\mu = 72$). In most substantive applications, researchers hope to demonstrate that this probability is small, and the observed sample estimate is unlikely to have arisen from a population as hypothesized in the H_0 . Although this example concerns a hypothesis about a population mean μ , hypotheses concerning any population parameters (e.g., variance, correlation coefficient, and proportion) are essentially the same. So we may express H_0 in a generic form:

$$H_0: \theta = K$$

where θ is the population parameter under investigation, and K is the hypothesized value of that parameter.

Directional and Nondirectional Alternative Hypotheses

Hypothesis testing involves two statistical hypotheses. The first is the null hypothesis (H_0) as described above. For each H_0 , there is an alternative hypothesis (H_a) that will be favored if the null hypothesis is found to be statistically not viable. The H_a can be either nondirectional or directional, as dictated by the research hypothesis. For example, if a researcher only believes the new instructional approach will have an impact on student test scores, but is unsure whether the effect will be positive or negative, the null and alternative hypotheses would be

$$H_0: \mu = 72$$

$$H_a: \mu \neq 72$$

Here, H_a reflects the researcher's uncertainty regarding the directionality, and it allows for a statistical test that considers both possibilities that the new instructional approach could increase test scores or decrease test scores. This is commonly referred to as a nondirectional alternative hypothesis, and is also referred to as a two-tailed test for reasons that are described below.

A directional alternative hypothesis, on the other hand, is useful to accommodate the researcher's prediction that, for example, the new instructional approach will decrease

test scores ($H_a: \mu < 72$ bpm) or will increase test scores ($H_a: \mu > 72$). A directional alternative hypothesis is often referred to as a one-tailed test as described below. It is important to note, however, that for every specified H_0 there will be a single H_a that may assume one of the three forms

$$H_a: \theta \neq K$$

$$H_a: \theta < K$$

$$H_a: \theta > K$$

Sample, Population, and Inferential Statistics

A sample is a subset of a population of interest that is defined by the researcher. For example, one could conceivably collect math achievement data on all fifth graders in the United States. However, given the limited resources, it is more realistic and economical to work with a subset of this group (i.e., sample), with the goal of generalizing the findings to the total population. It is possible, or even very common, that the population of interest is a statistical population that does not really exist. For example, our educator interested in the effectiveness of a new instructional approach may statistically compare two student samples: one sample receiving this new approach, and the other receiving the business-as-usual approach. In this situation, there are two hypothetical statistical populations: one population of students taught under this new approach, and another population of students taught under the business-as-usual instructional approach. In reality, we do not really have these two populations.

A sample statistic $\hat{\theta}$ is a measure of a sample characteristic (sample mean, proportion, correlation, etc.), whereas a measure of the corresponding population characteristic is a population parameter (θ). Researchers are typically interested in understanding the characteristics of a population, but it is often impossible or impractical to obtain data from the whole population (e.g., lack of resources to do so; or a hypothesized statistical population). Inferential statistics are useful for estimating population characteristics (i.e., parameters), and for generalizing the sample findings to the population from which the sample was drawn.

Hypothesis testing is at the center of inferential statistics. Both point estimation and interval estimation are commonly used first steps in the hypothesis testing process. In point estimation, a single population parameter value is hypothesized and used in hypothesis testing. By contrast, interval estimation serves as a useful supplement to point estimation because it provides a likely range of values for the unknown population parameter. The key to

both point and interval estimation is in estimating the sampling variability of a given sample statistic.

Sampling Distribution

In hypothesis testing, sampling variability (i.e., sampling error) of a sample statistic $\hat{\theta}$ is the foundation for estimating the probability of observing a sample statistic equal to or more extreme than what is obtained under the true null hypothesis. A statistic's sampling distribution provides the estimation for sampling error. For example, assume we are interested in the average performance on a math achievement exam (parameter) of all fifth graders in the United States (population). Our best estimate of the unknown population mean parameter (μ) would be the sample average (\bar{X}) based on a random sample of n observations from this population. If this process of drawing random samples of size n from the same population were repeated many times, the means from all the samples would vary, and these means themselves would form a distribution, which is called a sampling distribution of the mean. This sampling distribution concept also extends to other sample statistics (e.g., sample variance, proportion, and correlation).

This sampling distribution captures the sample-to-sample variability of a sample statistic. In the case of \bar{X} , theoretically, the average of all possible sample means, or the expected value of the statistic, $E(\bar{X})$, is equal to the population mean (i.e., μ). Statistics with this property, that is, $E(\hat{\theta}) = \theta$, are referred to as unbiased estimators.

Standard error

Sample-to-sample variability of a statistic, or sampling error, can be quantified by standard error. In the case of sample means as described above, the standard error of the mean quantifies the variability of the sampling distribution of the mean. When samples are randomly selected from a population, the resulting distribution will be approximately normally distributed for reasonable sample size of n (see the subsection titled 'Central limit theorem' below). When the population standard deviation (σ) is known, the standard deviation of the sampling distribution of means, usually referred to as standard error of the mean, is:

$$\sigma_{\bar{X}} = \frac{\sigma}{\sqrt{n}}$$

As is obvious, $\sigma_{\bar{X}}$ is a function of the sample size (n). As n increases, $\sigma_{\bar{X}}$ decreases to its lower limit of 0 (i.e., $n \rightarrow \infty, \sigma_{\bar{X}} \rightarrow 0$). Likewise, as sample size decreases, $\sigma_{\bar{X}}$ increases to its upper limit of the population standard deviation σ (i.e., $n \rightarrow 1, \sigma_{\bar{X}} \rightarrow \sigma$). In general, over repeated sampling, sample statistic $\hat{\theta}$'s based on a larger

sample size has less variability (i.e., less sampling error) than those based on a smaller sample size.

Central limit theorem

Several properties of sampling distributions that have important implications for hypothesis testing are captured in the central limit theorem (CLT). In a nutshell, CLT states the following. First, as the size (n) of the samples drawn from a population increases, the standard error of the means decreases, leading to less variability of sample means and smaller sampling error. **Figure 1** presents two sampling distributions of the means, one based on $n = 10$, and the other based on $n = 30$. As shown in **Figure 1**, the distribution based on a smaller sample size ($n = 10$) spreads out more than the one based on a larger sample size ($n = 30$).

Second, the shape of the sampling distribution of the mean becomes increasingly normal as the sample size increases. This is true regardless of the shape of the parent population from which the samples are drawn. As a result, the sampling distribution of \bar{X} can generally be considered as being normally distributed for samples of size $n = 30$ or greater, even though the parent population may not be normally distributed.

Sampling distribution as probability distribution

Hypothesis testing involves estimating the probability of observing a sample statistic ($\hat{\theta}$) equal to or more extreme

than what is obtained from a sample, assuming true H_0 . For this purpose, the sampling distribution of the statistic developed under H_0 serves as the probability distribution. Under this probability distribution, the closer the observed sample statistic (e.g., \bar{X}) is to the population parameter (e.g., $\mu = K$) under H_0 , the more likely that the difference between \bar{X} and μ may have been the result of sampling variation (i.e., sampling error). Sample statistic values near the tails of the sampling distribution represent a greater difference between the sample statistic and the population parameter under H_0 . These values occur less frequently in repeated sampling, and consequently, the probability of observing the sample statistic values near the tails is smaller. Under H_0 , if this probability is judged to be smaller than a predetermined threshold probability level (denoted α), we will conclude that H_0 is likely not true; if it were, it would be very unlikely to observe the sample statistic. Conventionally, $\alpha = 0.05$ is often used as such a threshold, leading to the following decision rules with regard to H_0 :

$$\text{If } p(\hat{\theta}|H_0) \leq \alpha = 0.05 \rightarrow \text{reject } H_0$$

$$\text{If } p(\hat{\theta}|H_0) > \alpha = 0.05 \rightarrow \text{fail to reject } H_0$$

This rule implies that when the observed sample statistic value becomes so rare under the H_0 sampling distribution (e.g., $p < 0.05$), we would be willing to conclude that the value specified in the H_0 is not a plausible population value for the observed sample statistic. It should be noted that this rule does not suggest that such sample statistic values cannot occur under H_0 ; it only states that values so extreme occur less frequently under H_0 . Moreover, there is nothing magical about the conventional $\alpha = 0.05$ decision rule: researchers may choose other values for evaluating H_0 , based on their considerations about type I and type II errors (described below). It is important to note that, given the observed sample statistic, hypothesis testing is unable to address the question of whether H_0 is true. The process only involves the determination of the probability of obtaining sample statistic values equal to or more extreme than the sample result under the assumption that H_0 is true (Cohen, 1994).

Test Statistics and Probability Estimates

In hypothesis testing, to assess the probability of observing values more extreme than a given sample statistic under H_0 , we translate the observed sample statistic value into a test statistic. For example, the test statistic for evaluating a single sample mean (\bar{X}) when the population standard deviation (σ) is known is:

$$Z_{obs} = \frac{\bar{X} - \mu}{\sigma_{\bar{X}}}$$

Figure 1 Two sampling distributions of the mean from the same population: $n = 10$ and $n = 30$.

Figure 2 Three t -distributions with $df = 5$, $df = 15$, and $df = \infty$.

This z_{obs} test statistic represents the distance between the sample mean and hypothesized population mean in standard deviation units, where the standard deviation is the standard deviation of the sampling distribution of the mean (i.e., standard error of the mean: (σ/\sqrt{n})).

A larger absolute value of z_{obs} is further away from the hypothesized population mean. The exact probability of observing a value of z_{obs} or larger can be obtained from a normal distribution table.

Application of the z test statistic requires that the population standard deviation σ be known. When σ is unknown and must be estimated with the sample standard deviation (s), the estimated standard error of the mean is $s_{\bar{X}} = \frac{s}{\sqrt{n}}$, and the test statistic becomes:

$$t_{\text{obs}} = \frac{\bar{X} - \mu}{s_{\bar{X}}}$$

In contrast to the single z distribution, there exists a family of t distributions, as defined by degrees of freedom (df) that are based on sample size ($df = n-1$). **Figure 2** presents three t distributions with different df ($df = 5$, 15 , or ∞). Because the t distributions have different shapes, probabilities beyond a given t value depend not only on the value of t , but also on the df on which that statistic is based. As sample size n increases, t distributions converge on the z distribution. Beyond $df = 120$, the difference between z and t distributions is negligible, and a t -test practically becomes a z -test.

Test statistics (e.g., F statistic, χ^2 statistic) other than z and t may be needed as required by a statistical analysis. Regardless of the specific test statistic used in a research situation, the logic and procedure described here for hypothesis testing remain the same.

Decision Rules Based on Test Statistic

The discussion above focused on testing H_0 by comparing the probability of obtaining sample statistic values more extreme than a given sample statistic, assuming the true

H_0 , against a predetermined threshold probability level (i.e., $\alpha = 0.05$). In practice, this is done through a direct comparison of the observed sample test statistic (e.g., z_{obs} , t_{obs} , F_{obs}) against the critical value of the statistic (e.g., z_{cv} , t_{cv} , or F_{cv}) as determined by the predetermined threshold probability level α . For example, the critical value of t (i.e., t_{cv}) associated with a given value of α and a given df is readily available from a table of t distributions. By comparing t_{obs} against t_{cv} , we can establish the following decision rule for testing H_0 :

$$\text{If } |t_{\text{obs}}| \geq |t_{\text{cv}}| \rightarrow \text{reject } H_0$$

$$\text{If } |t_{\text{obs}}| < |t_{\text{cv}}| \rightarrow \text{fail to reject } H_0$$

This decision rule is a direct translation of our previous probability-based decision rule for testing H_0 :

$$\text{If } p(\hat{\theta}|H_0) \leq \alpha \rightarrow \text{reject } H_0$$

$$\text{If } p(\hat{\theta}|H_0) > \alpha \rightarrow \text{fail to reject } H_0$$

For example, our educator researcher previously hypothesized mean student achievement test score of 72 for a population ($H_0: \mu = 72$), and she would like to test this H_0 against the nondirectional alternative hypothesis $H_a: \mu \neq 72$ for $\alpha = 0.05$. From a random sample of 100 participants, the researcher obtained $\bar{X} = 68$, and $s = 8$ (i.e., $s_{\bar{X}} = \frac{s}{\sqrt{n}} = 0.8$). The test statistic is:

$$t_{\text{obs}} = \frac{\bar{X} - \mu}{s_{\bar{X}}} = \frac{68 - 72}{0.8} = -5$$

As $|t_{\text{obs}}| = 5$ exceeds the $t_{\text{cv}} [t_{(.975, df=99)} = 2.28, \alpha = .05]$, the $H_0: \mu = 72$ is rejected, as it is very unlikely ($p < 0.05$) to observe sample mean values equal to or greater than $\bar{X} = 68$ if H_0 were true.

Either a nondirectional or directional alternative hypothesis may be evaluated. When a nondirectional alternative hypothesis is evaluated (i.e., $H_a: \mu \neq K$), the overall α (e.g., $\alpha = 0.05$) is evenly divided into the two tails of the sampling distribution of H_0 , to accommodate the possibility that the direction of difference between \bar{X} and μ can be either

Figure 3 The α at distribution tails for nondirectional (two-tailed) and directional (upper tail) tests.

positive or negative, as shown in **Figure 3** (two solid lines at the tails).

When a directional alternative hypothesis is used (e.g., $H_a: \mu > K$), we only consider the critical value at one tail that corresponds to the hypothesized direction in H_a , and the overall α is located at this tail, as shown in **Figure 3** (dashed line at the right tail for $H_a: \mu > K$). Nondirectional and directional alternative hypotheses are often referred to as two-tailed and one-tailed tests, respectively. For a directional (one-tailed) test, because all α is located at one tail, the critical value of the test statistic will be smaller in absolute value than that in a nondirectional test. For example, for a z -test with $\alpha = 0.05$, the critical values are ± 1.96 for a two-tailed test (nondirectional test), and the critical value for a one-tailed (directional) test ($H_a: \mu > K$) is only 1.65. This makes it easier for a one-tailed test to reject H_0 , as long as the test statistic is in the hypothesized direction. Because of this, if the test statistic is in the hypothesized direction, the one-tailed test has more statistical power (see description of statistical power below) over the two-tailed test. When the test statistic is *not* in the hypothesized direction, however, the test automatically fails to reject the H_0 .

Confidence Intervals in Hypothesis Testing

The hypothesis testing approach described above is a point-estimate approach that results in a dichotomous decision (i.e., reject or fail to reject H_0). On the other hand, interval-estimation approach provides a range of values within which a population parameter is likely to reside. The importance of using confidence intervals (CIs) in educational and psychological research has been emphasized by the American Psychological Association (APA) task force (Wilkinson and Task Force on Statistical Inference, 1999), and such emphasis has been reflected in

the guidelines in the APA publication manual as best practice in reporting empirical results (APA, 2001).

For a hypothesized population value θ , using the sample estimate $\hat{\theta}$, and for a given α , the following CI can be constructed:

$$100(1 - \alpha) C.I. = \hat{\theta} \pm T_{(1-\frac{\alpha}{2})} S_{\hat{\theta}}$$

(This is the classical definition of CI under true H_0 , where the critical values from a central distribution (e.g., central t distribution) are used to construct a symmetrical CI. However, if a true H_0 is not assumed, critical values from a noncentral distribution (e.g., noncentral t distribution) may be used for constructing the CI for the unknown population parameter θ , and this will result in a nonsymmetrical CI. For more details, readers may consult, e.g., Cumming and Finch (2001), Steiger and Fouladi (1997). where $T_{(1-\frac{\alpha}{2})}$ is the appropriate test statistic (e.g., z , t) value at the $100(1 - \frac{\alpha}{2})$ percentile point of its distribution, and $s_{\hat{\theta}}$ is the estimated standard error (i.e., $s_{\hat{\theta}} = \frac{s}{\sqrt{n}}$) of the sampling distribution. Adding and subtracting the quantity of $T_{(1-\frac{\alpha}{2})} s_{\hat{\theta}}$ from $\hat{\theta}$ results in the lower and upper limits of a $CI(\hat{\theta} - T_{(1-\frac{\alpha}{2})} s_{\hat{\theta}}, \hat{\theta} + T_{(1-\frac{\alpha}{2})} s_{\hat{\theta}})$ that has probability of $1 - \alpha$ of containing the unknown population parameter value θ . If the hypothesized population parameter value under H_0 is outside this CI, it leads to the rejection of H_0 . Conversely, if the CI contains the parameter value under H_0 , H_0 will not be rejected.

Using our previous example about a new instructional method, the researcher obtained $n = 100$, $\bar{X} = 68$, and $s = 8$ (i.e., $s_{\bar{X}} = \frac{s}{\sqrt{n}} = 0.8$). For $\alpha = 0.05$, $t_{(975, df = 99)} = 2.28$, the 95% CI would be (66.18, 69.82). (Lower limit is $68 - (2.28 \times 0.8) = 66.18$; upper limit is $68 + (2.28 \times 0.8) = 69.82$.) As this CI does not contain 72 under H_0 , the H_0 would be rejected. With a CI, we are not only

Figure 4 Fifty 95% confidence intervals for population parameter μ .

able to evaluate the H_0 (point estimation), but also able to estimate a range of probable population parameter values (interval estimation). The value of a CI is that, it provides information not only about the sample-based point-estimate, but also about the estimation error associated with the statistic. In the social sciences, the resulting estimation error may be large, and this may explain why such intervals are not often reported (Cohen, 1994).

It is important to note that this 95% CI does not indicate that we can be 95% confident that this interval contains the population parameter (see Thompson, 2007: 427). Rather, this is interpreted to mean that 95% of similarly constructed intervals will contain the population parameter, while 5% of them will not. This is illustrated in **Figure 4** for a hypothetical situation where 50 random samples were drawn from a population with parameter μ , and a 95% confidence interval was constructed from each sample. Out of the 50 CIs, 47 contained the population parameter, and three did not.

Statistical Errors (Type I and Type II) and Power

In hypothesis testing, two types of statistical errors may occur: reject H_0 when it is true (type I error), or fail to reject H_0 when it is false (type II error). On the other hand, a correct decision is made when a true H_0 is not rejected, or when a false H_0 is rejected. These possible outcomes in hypothesis testing are shown in **Figure 5**.

		Decision based on sample data	
		Reject H_0	Fail to reject H_0
True state of nature	H_0 true	Type I error α	Correct decision $1-\alpha$
	H_0 false	Correct decision (power) $1-\beta$	Type II error β

Figure 5 Hypothesis testing errors and correct decisions.

Figure 6 Type I, type II errors and statistical power.

In a hypothesis test, once a decision is made with regard to H_0 , either a type I error (when H_0 is rejected), or a type II error (when H_0 is not rejected), is possible, but not both. We cannot know with certainty whether the decision is actually an error. When H_0 is rejected, only a type I error is possible. The probability for a type I error is known, because it is directly controlled by the researcher through the choice of the α level (e.g., $\alpha = 0.05$), which represents the risk we are willing to take in concluding that the H_0 is false when it may be true. On the other hand, when H_0 is not rejected, only a type II error is possible. Here, the probability for a type II error is unknown, but can be estimated, and is generally not directly controlled by the researcher. In **Figure 5**, when H_0 is true (upper row), the probability for a type I error is α , and the probability of making a correct decision (i.e., not to reject the true H_0) is $1 - \alpha$. When H_0 is false (lower row), the probability for a type II error is β , and the probability of making a correct decision (i.e., to reject the false H_0) is the power of a statistical test ($1 - \beta$).

Figure 6 graphically illustrates two sampling distributions under H_0 and H_a , respectively, as well as the relationships among the probabilities of type I and type II errors, and the statistical power (probability to reject a false H_0). The sampling distribution under H_0 represents all possible values of a statistic, including those in the specified region of α (vertically shaded area under H_0 to the left of the vertical dashed line) where a decision to reject H_0 would be made. This probability is often set at 0.05 to indicate that there is a 5% chance of rejecting a true H_0 (i.e., making a type I error).

Now consider the sampling distribution under H_a , which overlaps with that under H_0 . Sample-based test statistics in the type II error or β region (horizontally shaded area under H_a to the right of the vertical dashed line) would not lead to the rejection of H_0 , even though these sample statistics may in fact belong to the sampling distribution of H_a . As shown in **Figure 6**, statistical power (i.e., the probability to reject a false H_0) denoted by $1 - \beta$, is the area under H_a to the right side of the vertical dashed line defined by α .

Education researchers may desire to have a reasonable level of power (e.g., $\beta \approx 0.80$) for a statistical test. One way to increase statistical power is to increase α (e.g., from 0.05 to 0.10). Imagine the rejection line (vertical dashed line) in **Figure 6** sliding to the left to accommodate a higher α level (i.e., higher probability of making a type I error), and this would result in reducing type II error probability (β) and in increasing statistical power ($1 - \beta$). Conversely, decreasing α (e.g., from 0.05 to 0.01; sliding the rejection line under H_0 distribution to the right) will result in an increase in type II error probability (β) and a decrease in statistical power. Statistical power can also be increased by using larger sample sizes. Other things being equal, larger sample sizes lead to smaller standard errors of the distribution. Consequently, there will be less overlap between the distribution under H_0 and that under H_a , thus a smaller β , and more power (i.e., $1 - \beta$ is larger). Finally, an increase in statistical power can also come by way of greater treatment effects or greater separation between

the H_0 and H_a distributions. Researchers need to understand such interplay among type I error, type II error, and statistical power, and consider the relative cost and consequence of one type of error versus another in a given substantive research application.

Instrumental Variables

Introduction

The problem of identifying causal impacts is central to educational research and policy analysis. As educators and researchers study educational phenomena or programs, they often are trying to identify specific actions or agents that cause improved outcomes in students, schools, and communities.

Identification of causal effects relies on our ability to estimate unbiased relationships between an outcome (i.e., the dependent variable) and an agent (i.e., the independent variable), and there are many threats to unbiased estimation. For example, selection bias, omitted variables, measurement error, and reverse causality (i.e., the dependent variable actually influencing the independent variable) can lead to biased estimation and faulty inference.

There are many techniques that can help researchers identify causal impacts. Experimental methods, selection-correction models, regression-discontinuity approaches, and instrumental variables (IVs) are just examples of common techniques that researchers can use to estimate unbiased relationships between an outcome and a causal agent.

This article aims to focus on one of these tools, IVs. Our goal is to provide a simple overview of IVs, its key assumptions, and its potential to produce unbiased estimates. Further, the article provides several examples of how IVs estimation has been applied to educational research. The article discusses some of the limitations of IVs and some of the issues and limitations that researchers should be cognizant of when employing IVs.

This article does not intend to produce a technical review of IVs. A number of textbooks (e.g., Wooldridge, 2006; Greene, 2008) provide a basic introduction to IVs and the underlying math. In addition, there are several other reviews that discuss the notion of causality (e.g., Angrist *et al.*, 1996), experimental and quasi-experimental approaches (e.g., Angrist and Krueger, 2001), and parametric approaches to overcoming selection (e.g., Heckman, 1979). The goal is to provide a simple introduction and primer to educational researchers who are beginning to understand and to utilize this promising tool.

Instrumental Variable Estimation

Inconsistent Estimation in Ordinary Least Squares

Suppose that the true relationship between academic achievement and private schooling is given by the following equation:

$$Y_i = a + bP_i + cA_i + u_i \quad [1]$$

where Y_i is the academic achievement of student i , P_i is an indicator for whether student i attends private schooling, A_i is the ability of student i , and u_i is the residual. If an econometrician observes measures of Y , P , and A , he/she could estimate eqn [1] in an unbiased way. However, ability is hard to measure, and an econometrician may not observe it.

The naive econometrician may push forward and estimate the following production function of education:

$$Y_i = a + bP_i + v_i \quad [2]$$

The ordinary least squares (OLS) estimator, in this case, will clearly be inconsistent so long as private schooling and ability are correlated. We can see the inconsistency if we take the probability limit of the OLS estimator as n approaches infinity.

$$\text{plim}[\hat{b}] = b + c^* \text{plim} \left[\frac{\sum_{i=1}^n P_i A_i}{\sum_{i=1}^n P_i^2} \right] \neq b \quad [3]$$

This is a classic and simple example of omitted variable bias. OLS yields inconsistent estimates due to the violation of the classical assumption that the independent variable is independent of the error term, or – in other words – as n approaches infinity, the correlation between P and A does not converge to zero.

How do we then estimate b in lieu of the missing variable? One solution is IVs. We must find another variable that meets two conditions. First, the new variable must influence P , and second, the new variable must be uncorrelated with A (or any other variable that may be part of u_i in eqn [1]). This variable is called an instrument.

Identification

Presented, in this article, is an example of omitted variable because – in educational phenomenon, generally speaking – omitted variable bias is often ignored although likely to be present. Most textbooks (e.g., Greene, 2008) focus on the more general case of simultaneous equation systems. Economists have long recognized the problem of estimating parameters in simultaneous equation systems. Haavelmo (1943), for example, demonstrated that simultaneous equation systems may be unsolvable without additional exogenous variation. This exogenous variation is variation in an independent variable that helps predict one or more of the dependent variables in the model. Suppose that we augmented the

true model in eqn [1] with another equation reflecting the decision to enter private schooling:

$$P_i = f + gZ_i + bA_i + w_i \quad [4]$$

where Z_i represents a variable that influences the likelihood that student i attends private school. Rouse (1998), for example, used the offer of an educational voucher program as the Z variable in an equation similar to eqn [4]. Neal (1997) uses access to Catholic schools as an instrument to find out whether students attended private schooling.

If we consider the system of equations in eqns [1] and [4], there are two endogenous variables – private schooling and student achievement. These variables are determined completely by the system of equations. There are also two exogenous variables – ability and the Z variable. These variables are taken as given and not influenced by the other variables in the model. Together, the system of equations would be referred to – in the academic literature – as the structural model. The system could be solved to make each endogenous variable a function only of the exogenous variables. This system of equations (eqns [5] and [6]) is known as the reduced form.

$$\begin{aligned} Y_i &= (a + bf) + (bg)Z_i + (c + bh)A_i + (u_i + bw_i) \\ &= j + kZ_i + mA_i + e_i \end{aligned} \quad [5]$$

$$P_i = f + gZ_i + bA_i + w_i \quad [6]$$

Equation [6] is identical to eqn [4] since the endogenous variable of private schooling was already a function of all of the exogenous variables in our model. (If either student achievement or another endogenous variable had influenced private schooling in eqn [4], then eqn [6] would have differed from eqn [4].) Equation [1], however, has now been transformed to include Z and to eliminate the other endogenous variable from the model.

In our structural model, eqn [1] shows student achievement as a function of another endogenous variable, private schooling. The coefficient on private schooling (b) is the key coefficient that we seek to identify. One might notice that the ratio of the coefficients on the Z variable in the reduced form would help us measure b . The method of using the ratio of coefficients to identify the structural coefficients is called indirect least squares.

When we refer to the state of identification of eqn [1], there are three possible states. The model could be unidentified, just identified, or over identified. The state of identification varies from equation to equation in the structural model and depends on a comparison of the number of included right-hand-side endogenous variables and the number of excluded exogenous variables. For example, eqn [1] has one right-hand-side endogenous variable (P) and one excluded exogenous variable (Z). When the number of included endogenous variables is equal to the number of excluded exogenous variables, then the

equation is just identified. If Z represented a matrix of excluded exogenous variables, then we would have more exogenous variables (i.e., the rank of Z) than included endogenous variables (P). Equation [1] would then be over identified. If Z did not enter the model, then the model would be unidentified.

IVs Estimation

For a variable to be a good instrument, there are two conditions that must hold. First, Z must be related to the endogenous variable we are trying to predict. For example, in eqn [4], we need the coefficient g not to be equal to zero. Asymptotically, we would say that

$$\text{plim}[Z'P] \neq 0 \quad [7]$$

There has been some discussion in the academic literature concerning the case where the eqn [7] is satisfied, but the covariance between Z and P is close to zero. This case of weak instruments is discussed below.

It can easily be tested whether eqn [7] is satisfied by estimating the first stage of the equation. The first stage of this discussion would be eqn [6]. This could estimate this regression and examine the coefficient g . There are a number of indicators in this first stage that the investigator could report to denote the fit. They could report the t -statistic on the instrument or the R-squared of the equation. The econometrics literature typically relies on the F -statistic testing the joint hypothesis that the coefficients on all of the instruments (i.e., the excluded exogenous variables from eqn [1]) are zero. An F -statistic over ten suggests that the instrument has good explanatory power and that eqn [7] is satisfied.

The second condition required in IV estimation is the exclusion restriction. This restriction is more limiting and generally untestable. The second restriction assumes that

$$\text{plim}[Z'v] = 0 \quad [8]$$

where v derives from eqn [2] and includes any variable that is not included in the regression that affects student achievement. In the present case, there is collapsed ability into the error term since ability is unobserved.

The exclusion restriction, essentially, means that the instrument (Z) does not directly affect the outcome of interest (Y) except through its influence on the right-hand-side endogenous variable (P). Because the exclusion restriction is untestable, it is an obvious source of debate in many papers. Defending an instrument is difficult, and authors, generally, need to think carefully through the instruments' potential correlations with other confounding variables. For example, Rouse (1998) used educational vouchers as an instrument for private school attendance. Angrist *et al.* (2002) were reluctant to do this since most of the families in their sample attended private school anyway. In their

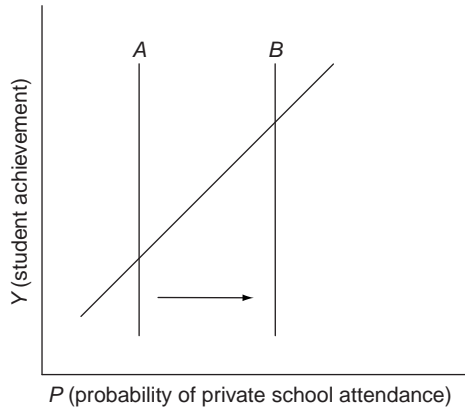

Figure 1 Graphical example of shift in the instrument.

case, the voucher – while correlated with private school attendance – was also a significant boost in the incomes for many families who would have sent their children to private schools irrespective of the voucher. The increase in incomes could have independently affected student achievement.

Concern over the exogeneity of instruments and the exclusion restriction has helped fuel movements toward experiments and natural experiments in economics (Angrist and Krueger, 2001). In the case of experiments, randomization often determines participation. By construction, randomization should be exogenous from the outcomes of interest while influencing the treatment under investigation.

If the instrument is related to the treatment of interest and uncorrelated with our outcome of interest, then the model can be estimated. The model essentially includes two stages. The first stage has been discussed above. In this step, the variation in Z is used to predict P . In the second stage, the predicted value of P is used to estimate the relationship between P and Y .

Figure 1 provides an illustration of the IVs set-up. The upward-sloping line maps the relationship between private school attendance and achievement. The slope is the underlying value of ' β ' in eqn [1]. It is not drawn upward sloping, but it could just as likely be negative sloping. The vertical line ' A ' represents the predicted probability that a person attends private school. Movements in Z cause the probability of private school attendance to increase – leading to a shift from line ' A ' to line ' B '. The outward shift causes variation in student achievement, which allows the measurement of the slope of relationship between achievement and private schooling. The first IV assumption assures that the probability of private schooling depends on the instrument – hence, the outward shift in the schedule. The exclusion restriction assures that only the private school schedule is shifting. If the exclusion restriction was not met and Z influenced student achievement, then the sloped line showing the relationship between P and Y

would have shifted outward as well, and it would have been impossible to measure the slope of this schedule.

In practice, the IVs estimate is defined as

$$\hat{b}_{IV} = (P'Z(Z'Z)^{-1}Z'P)^{-1}P'Z(Z'Z)^{-1}Z'Y \quad [9]$$

In the simple case where Z represents only one variable, **Equation 9** simplifies to

$$\hat{b}_{IV} = (Z'P)^{-1}Z'Y \quad [10]$$

The more general case, in eqn [9], is useful since it could incorporate a more complex system with several instruments.

The standard errors can easily be computed in a single step, assuming independence of the observations and no heteroskedasticity.

$$V(\hat{b}_{IV}) = \hat{\sigma}^2(P'Z(Z'Z)^{-1}Z'P)^{-1}. \quad [11]$$

As in other statistical applications, standard errors can be adjusted for clustering and heteroskedasticity.

Other Considerations in Estimation

Weak Instruments

Angrist and Krueger (1991) wrote one of the most influential papers utilizing IVs. Angrist and Krueger attempted to identify the effects of a high school education on individual's earnings. They recognized that there may be important omitted variables (e.g., ability) that prevent using OLS. Angrist and Krueger recognized that there was variation across states in the compulsory schooling laws and that there was variation in entry dates in school that was correlated with the quarter in which students were born. As a result, students in some states may acquire more years of education before they can drop-out than students in other states. The exact impact on the total number of years of schooling depends on the quarter of birth and the state of birth. Hence, the interaction between quarter of birth and individual state's of birth provides a set of instruments that can predict the number of years of completed schooling. The authors find that an additional year of schooling led to a 9% increase in income. Their use of census data gave them a large sample, and, thus, the estimate was quite precise.

Bound *et al.* (1995) focused on the weak correlation of the instruments in the Angrist and Krueger study with the endogenous regressor of interest (years of schooling). Bound and co-workers replicated Angrist and Krueger's results, but they also generated a random variable based on a similar distribution as the quarter of birth instrument. By construction, the random instruments are unrelated to the number of years of schooling. Nonetheless, the IVs estimates based on this exercise generated estimates that

were, often, statistically significant. The large samples used in these studies were the key. The significance in the first stage relied more heavily on the large-sample properties of the estimators than on the strength of the underlying economic relationships of the variables.

Staiger and Stock (1997) attempted to formalize some empirical rules for identifying the behavior of IV estimates. They argue that the first-stage F -statistic testing that all of the instruments are simultaneously equal to zero is the best indicator of potential weak-instruments problems. Through a number of Monte Carlo simulations, they find that an F -statistic greater than ten indicates that there is no weak-instrument problem. Without an F -statistic greater than ten, the IV estimates are biased toward the OLS estimates. The F -statistic greater than ten has become a rule of thumb for empiricists using IV. However, research on weak instruments and on improving estimation techniques in IV models with weak instruments remains an area of active exploration.

Local Average Treatment Effect (LATE) Interpretation

Another feature of the Angrist and Krueger (1991) paper was that the variation in years of completed schooling was being generated by a set of individuals who, generally, desired to withdraw from school during high school. Imbens and Angrist (1994) examined situations in which causal impacts were being generated by the behavior of a subset of individuals. Their work formalized the local average treatment effect (LATE) interpretation of IVs (see also Angrist *et al.*, 1996).

The key insight in this work is that there could be heterogeneous effects of a treatment on different sets of the population. IVs estimates show the average effect of treatments on individuals for whom the instrument influences individuals' behaviors (i.e., treatment compliers – in the Imbens and Angrist terminology). In the case of the Angrist and Krueger study, less than 2% of the population were compliers (i.e., years of education were influenced by compulsory schooling laws and quarter of birth) (Imbens, 2007). Given the small proportion of the population that generated these estimates, the estimated effects may not generalize to the overall population.

Specification Tests

While we can rarely test the exclusion restriction, researchers often employ Hausman specification tests in IVs models to test certain aspects of the models (Hausman, 1978, 1983). Hausman specification tests generally compare two estimates. Under the null hypothesis, both sets of estimates are consistent, but one is more efficient. Under the alternative hypothesis, only one set is consistent.

First, Hausman tests can be used to compare OLS and IV models. Under the null hypothesis, the OLS

assumptions are not violated. In this case, both OLS and IV yield consistent estimates, but OLS is more efficient. Under the alternative hypothesis of endogeneity, IV is consistent. In our simple example, one could estimate eqn [2] with OLS and IV (using Z as the instrument). The comparison of the coefficients and their corresponding standard errors gives the Hausman test.

Second, Hausman tests are often used to test over-identifying restrictions. Researchers can compare an IV model that is just identified to one where all of the available instruments are used in the estimation. If the IV estimates are similar, then the instruments seem to be valid. If the IV estimates are different, then some of the instruments may be invalid. The test does not shed light on which instruments are problematic and states only that some might be problematic.

Examples of IV Estimation in Education

Returns to Schooling

Economists have, for long, studied the effects of schooling on earnings. In the case of earnings, economists consider a simple model comparing earnings (Y) to years of schooling (S).

$$Y_i = a + bS_i + u_i \quad [12]$$

$$S_i = a + bZ_i + v_i \quad [13]$$

As Griliches (1977) describes, there are a number of reasons why estimating eqn [12] with OLS will lead to biased results. For example, there is an inherent omitted variable as ability is left out of eqn [12] and is, likely, correlated with students' schooling choices. There could also be endogeneity in the schooling and earnings decisions since families are optimizing.

Card (2001) reviews papers published in the 1990s using IVs to estimate the effects of schooling on earnings. To overcome the biases described by Griliches (1977), the studies reviewed by Card utilized characteristics of the schooling system as instruments for the years of schooling. Specific features of schooling systems seemingly affected the overall years of schooling completed and may have been uncorrelated with earnings (see also the discussion in Kling, 1999).

The instruments in the studies reviewed by Card (2001) are as follows:

Interaction of quarter of birth with state and year of birth

As discussed above, this was the instrument used by Angrist and Krueger (1991) and subsequently investigated by Bound *et al.* (1995) and Staiger and Stock (1997). Bound *et al.* (1995) discuss limitations to this

instrument including the case for why this instrument may not satisfy the exclusion restriction.

Distance to school

There have been several permutations of this instrument. Kane and Rouse (1993) used the distance to the nearest college. Card (1995) and Conneely and Uusitalo (1997) used the presence of a university in a specific year. The main idea is that students living closer to schools have more access to them and complete more schooling (see also Maluccio, 1997).

Compulsory school laws

This certainly played a part in Angrist and Krueger (1991). It has also been used by Harmon and Walker (1995). Compulsory schooling laws create variation in the number of years completed (see also Devereux and Hart, 2008).

Military service or benefits

The most prominent paper in this vein Angrist (1992) actually focuses on the effects of military service on earnings, using the Vietnam draft lottery as an instrument. More recent studies (e.g., Angrist and Chen, 2007) have shown that the impact on earnings, likely, went through the impact of military service on educational choices that were influenced by G. I. Bill Benefits. Military experience has also factored into the instruments used in Ichino and Winter-Ebmer (1998) and Lemieux and Card (1998).

Other institutional features

Many authors have identified other shifts in schooling caused by natural experiments. Meghir and Palme (1999) used a change in the schooling system. Duflo (1999) used geographic indicators for regions with targeted school-building programs in Indonesia.

While our list and then number of studies we cite are clearly not all inclusive, the range of instruments should provide some examples of the instruments used to predict schooling choices.

Class Size

Another area where economists have used IVs to identify the impacts of a particular educational intervention is the effects of class size on student outcomes. While class size (C) may affect student achievement (Y), class size and student achievement may be endogenously determined.

$$Y_i = a + bC_i + u_i \quad [14]$$

$$C_i = a + bZ_i + v_i \quad [15]$$

Maimonides' rule

In recent years, the most popular IV for class size has been Maimonides-type rules. Angrist and Lavy (1999) use

Maimonides' rule as an instrument for class size. Maimonides' rule was established in the twelfth century. It stated that class sizes should not exceed 40; hence, in Israel today, schools hire an extra teacher when the class size reaches 40. The rule creates a systematic relationship between enrolment and class size. The Maimonides' rule is likely exogenous – or in other words – it can only impact achievement through its effect on class size. Maimonides-like rules have been used to measure class-size effects in other places such as France (Gary-Bobo and Mahjoub, 2006) and Bolivia (Urquiola, 2001).

Tennessee STAR

A series of papers were written, in the late 1990s, which examined Tennessee's class-size experiment. Schanzenbach (2007) reviews these studies. The Tennessee STAR experiment used randomization to determine the size of classes that individual students attended. While some studies have expressed some worry with regard to either the fidelity of the randomization or the possibility of Hawthorne effects (e.g., Hoxby, 2000), the randomization in STAR is an important instrument being used to measure the effects.

Demographic variation

Hoxby (2000) uses variation in the population. She examines a set of schools where year-to-year variation leads to discrete shifts in the number of classrooms used. Bettinger and Long (2008) use variation in the number of students actually enrolling in college with interest in a specific major as an instrument for class sizes in that major during a particular year.

As in the previous case, the number of studies we cite merely scratches the surface and provides some examples of the instruments used to predict class sizes.

Conclusion

This article is intended to be an introduction to IVs. There are several excellent textbooks (e.g., Greene, 2008) or literature reviews (e.g., Angrist and Krueger, 2001) where the interested reader can learn more. The spatial constraints in this volume as well as the vastness of the technique, its applications, and its interpretation prevent us from a more expansive review.

In education, the surge of papers using IVs has increased dramatically in the last two decades. As Griliches (1977: 2) quipped in a different setting, the number of papers employing IVs has become "a vast river of econometric studies threatening to engulf us all." Caution is always warranted in assuring that instruments truly meet the strict exogeneity assumptions and in the interpretation of these estimates.

Glossary

Bias – Deviation between the mean of a sample estimate and the true population value.

Sample estimate – A function of sample data used for approximating a population parameter.

Standard error – The square root of the average squared deviation between a true parameter value and its sample estimate.

The jackknife method is one of the most popular resampling methods. The method was suggested by Quenouille (1949) and further developed by Tukey (1958).

If the statistical model is too complex or not adequately known, it is often difficult to use a theoretical approach to compute the standard error or bias of a statistical estimate $\hat{\theta}$. The jackknife method or jackknifing may be used in such situations to estimate one or both of the bias and standard error of the estimate. The basic idea behind the jackknife method lies in systematically recomputing the estimate leaving out one observation or a group of observations at a time from the sample available to the investigator. The bias and the standard error of $\hat{\theta}$ can be computed from this new set of recomputed estimates (also called jackknife replications).

Description of the Jackknife Method

This section describes the jackknife method for the simple case when the data set contains values of one variable. Denote the available sample (of size n) as $\mathbf{x} = (x_1, x_2, \dots, x_n)$. For example, x_j could be the score of Student j on an educational test. Suppose that the interest is in estimating a parameter θ (e.g., θ could be the mean test score for the student population of interest) and the estimate of θ computed from the sample is denoted as $\hat{\theta}$ (e.g., $\hat{\theta}$ could be the sample mean). Suppose that the interest is in estimating the bias and standard error of $\hat{\theta}$. (Note that the bias and standard error of the sample mean is easy to compute theoretically; we are using this simple example only to illustrate the jackknife method.) The jackknife method creates jackknife samples $\mathbf{x}_{(i)}$ that leave out one observation at a time: $\mathbf{x}_{(i)} = (x_1, x_2, \dots, x_{i-1}, x_{i+1}, \dots, x_n)$ for $i = 1, 2, \dots, n$. In other words, the method leaves out the first sample observation to create

the first jackknife sample $\mathbf{x}_{(1)} = (x_2, x_3, \dots, x_n)$, then leaves out the second observation to create the second jackknife sample $\mathbf{x}_{(2)} = (x_1, x_3, x_4, \dots, x_n)$, and so on to finally leave out the last observation to create the n th jackknife sample $\mathbf{x}_{(n)} = (x_1, x_2, \dots, x_{n-1})$. Then the jackknife method computes the value of $\hat{\theta}$ for each of the jackknife samples. That is, it computes $\hat{\theta}_{(i)}$, $i = 1, 2, \dots, n$, where $\hat{\theta}_{(i)}$, which is called the i th jackknife replication, denotes the value of $\hat{\theta}$ computed from the i th jackknife sample $\mathbf{x}_{(i)}$. For example, when $\hat{\theta}$ is the sample mean, $\hat{\theta}_{(i)}$ is the mean of $\mathbf{x}_{(i)}$.

Let us denote

$$\hat{\theta}_{(\cdot)} = \frac{1}{n} \sum_i \hat{\theta}_{(i)}$$

Then, the jackknife estimate of bias of $\hat{\theta}$ is given by

$$\widehat{\text{bias}}_{\text{jack}} = (n-1)(\hat{\theta}_{(\cdot)} - \hat{\theta}).$$

The jackknife estimate of the standard error of $\hat{\theta}$ is given by

$$\widehat{\text{se}}_{\text{jack}} = \left[\frac{n-1}{n} \sum_i (\hat{\theta}_{(i)} - \hat{\theta}_{(\cdot)})^2 \right]^{1/2}.$$

Thus, the jackknife estimate of the bias is a multiple of the average of the jackknife deviations

$$\hat{\theta}_{(i)} - \hat{\theta}, i = 1, 2, \dots, n,$$

while the jackknife estimate of the standard error is a multiple of the sample standard deviation of the jackknife replications of the estimate $\hat{\theta}$ (see, for example, Efron and Tibshirani (1993), for a theoretical explanation of why the above bias and standard error estimates work well in many situations).

The quantity

$$\tilde{\theta}_i = n\hat{\theta} - (n-1)\hat{\theta}_{(i)}$$

is sometimes called the i th pseudo-value (e.g., Efron and Tibshirani, 1993). It can easily be shown that

$$\widehat{\text{se}}_{\text{jack}} = \left[\frac{1}{n(n-1)} \sum_i (\tilde{\theta}_i - \bar{\tilde{\theta}})^2 \right]^{1/2},$$

where $\bar{\tilde{\theta}} = \sum_i \tilde{\theta}_i / n$, so that $\widehat{\text{se}}_{\text{jack}}$ looks like an estimate of the standard error of the mean for data $\tilde{\theta}_i$, $i = 1, 2, \dots, n$. Thus, the pseudo-values act as if they are n independent observations.

Example 1: Population Mean

If θ is the population mean, $\hat{\theta} = \bar{x}$, the sample mean. The i th pseudo-value in this case is the same as x_i , the i th sample observation. In this case, $\hat{\theta}_{(\cdot)} = \bar{x}$ so that $\widehat{\text{bias}}_{\text{jack}} = 0$, which is expected as the sample mean is an unbiased estimator of the population mean. For this case,

$$\widehat{\text{se}}_{\text{jack}} = \left[\frac{1}{n(n-1)} \sum_i (x_i - \bar{x})^2 \right]^{1/2},$$

which is exactly the same as the unbiased estimate of the standard error of the mean.

Example 2: Population Variance

If θ is equal to the population variance $\sigma^2 = \int (x - E(x))^2 dF(x)$ and $\hat{\theta}$ is the sample variance $\sum_i (x_i - \bar{x})^2 / n$, then $\hat{\theta}$ has a bias of $-\sigma^2/n$. In this case,

$$\widehat{\text{bias}}_{\text{jack}} = -\frac{1}{n(n-1)} \sum_i (x_i - \bar{x})^2,$$

which is the unbiased estimate of the population variance multiplied by $-1/n$.

Jackknife Method for Multiple Variables

Often, multiple variables are observed for each individual, for example, in a study of the correlation coefficient among two variables or the regression of one variable on several other variables. In this case, the jackknife method proceeds in a similar manner as described in the case of one variable. The method leaves out all observations from one individual at a time and computes the estimate of interest based on all the information on the other $(n-1)$ individuals. Finally, the bias and standard error are computed as described above.

Example: Correlation and Regression

Table 1 shows the scores of 15 examinees on the Reading and Listening sections of an English test. The score is the number of correct answers in 50 multiple choice questions. The correlation coefficient between the two scores is 0.733. The jackknife estimate of bias of the correlation coefficient is -0.003 , which is somewhat smaller in magnitude than the estimate of the bias (-0.014) from theoretical calculations (Olkin and Pratt, 1958). The jackknife estimate of the standard error of the correlation coefficient is 0.141. In a linear regression of the listening score on the reading score, the regression coefficient for the reading score is 0.52 with a corresponding standard error estimate of 0.13. The jackknife estimate of the bias and standard error of the regression coefficient is 0.02 and 0.18, respectively.

Table 1 Scores of 15 examinees on the Reading and Listening sections of an English test

Examinee	Listening	Reading
1	35	31
2	46	35
3	36	30
4	36	22
5	49	37
6	41	30
7	40	21
8	41	33
9	45	34
10	44	31
11	33	21
12	39	15
13	49	42
14	35	25
15	36	22

Deleted- d and Grouped Jackknife

The jackknife method described above is also called the leave-one-out jackknife or deleted-1 jackknife as it leaves or deletes one observation at a time to obtain the jackknife samples. It is possible to leave out d observations (where $d > 1$) at a time to obtain deleted- d or deleted- d or delete- k jackknife samples. The size of the jackknife samples in this case is $(n-d)$ and there are $\binom{n}{d}$ such jackknife samples. Let $\hat{\theta}_s$ denote the estimate of $\hat{\theta}$ computed from the data set after subset s is removed. The formula for the deleted- d jackknife estimate of standard error is

$$\widehat{\text{se}}_{\text{jack}} = \left[\frac{n-d}{d \binom{n}{d}} \sum_s (\hat{\theta}_s - \hat{\theta}_{(\cdot)})^2 \right]^{1/2},$$

where $\hat{\theta}_{(\cdot)} = \sum_s \hat{\theta}_s / \binom{n}{d}$.

The deleted- d jackknife is often preferred over the deleted-1 jackknife method (Efron and Tibshirani, 1993; Shao and Tu, 1995). One such situation is the application of nonsmooth statistics. (When small changes in the data set cause only small changes in a statistic, it is called a smooth statistic. An example of such a statistic is the sample mean. An example of a nonsmooth statistic is the sample median.) For example, a deleted- d jackknife estimate is better (in terms of achieving consistency) than the deleted-1 jackknife estimate for the sample median.

Usually, d should be more than the square root of n . When n is large, the number of jackknife samples can be large. A practical choice will be not to consider all $\binom{n}{d}$ deleted- d jackknife samples, but divide the observations into roughly $\frac{n}{d}$ groups of size d and leave out one group at a time to obtain roughly $\frac{n}{d}$ jackknife samples. This variation of the deleted- d jackknife is referred to as the grouped jackknife method (e.g., Miller, 1964). The grouped jackknife method is stable, although slightly

less efficient, when compared to the deleted- d jackknife method, but it is much less computationally intensive for large samples (Miller, 1964, 1968). Another option often recommended when n is large is to choose a random sample of the jackknife samples.

Jackknife versus Bootstrap

Both the bootstrap and the jackknife are examples of resampling methods and estimate the variability of a statistic from the variability of that statistic across subsamples, rather than from parametric assumptions. The jackknife is easier to apply to complex sampling schemes, such as multistage sampling with varying sampling weights, than the bootstrap. On the other hand, the bootstrap is usually less computationally intensive for large samples.

The jackknife and bootstrap may often yield similar results. But when used to estimate the standard error of a statistic, the bootstrap gives slightly different results when repeated on the same data, whereas the jackknife gives exactly the same result each time. This is because the bootstrap involves drawing random samples from the sample observations while the jackknife does not involve any randomness.

Application of the Jackknife Method to the National Assessment of Educational Progress

The National Assessment of Educational Progress (NAEP; see, e.g., von Davier *et al.*, 2007) is an ongoing survey of the performance of school students in the U.S. in a number of subject areas, including reading, writing, and mathematics. NAEP fits a complicated item response theory model to the data and computes the estimated proficiencies of several demographic groups (such as Black students and female students) in several subject areas and the corresponding variance estimates. It is not straightforward to compute the variance estimates using standard statistical theory. Jackknife estimates of sampling variance form a portion of the variance estimates.

For example, in NAEP 1998, 62 pairs of primary sampling units (PSUs) were involved. A PSU usually refers to a geographical area in the US. The pairs were composed so that PSU pairs were relatively similar in socioeconomic makeup. In turn, a pair was chosen from the 62 PSU pairs, a single PSU was dropped from the pair, and the estimate (of the mean proficiency of a demographic group on a subject area) was calculated. Let $\hat{g}_G^{(l)}$ denote the estimate obtained when a PSU is dropped from l th PSU pair.

The NAEP jackknife estimate of sampling variance for the group and subject area, denoted V_G , is defined as

$$V_G = \sum_{l=1}^{62} \left(\hat{g}_G^{(l)} - \tilde{g}_G \right)^2$$

where \tilde{g}_G is the estimate of the group mean from the full sample.

For other applications of the jackknife method to educational research, see von Davier *et al.* (2008), Qian (2006), and Longford (1992).

Concluding Remarks

The jackknife method is a popular resampling method that provides estimates of the bias and a standard error of an estimate by recomputing the estimate from subsamples of the available sample. The method has some similarities to the bootstrap method, but may provide different results from bootstrap in real applications. The method is relatively straightforward and hence can be useful in applications where theoretical statistics cannot readily provide estimates of the bias or standard error of an estimate. Such an example, of an application of the jackknife method to NAEP, is briefly described in this article.

Introduction

In a broad sense, the objective of statistical inference is to draw conclusions about some characteristics of a (possibly conceptual) population of interest based on the information obtained from a sample conveniently selected therefrom. Most commonly, these characteristics correspond to parameters, such as the mean or the variance, but they may also involve more general features of the population, such as the associated (frequency) distribution itself. In general, the strategy for inference involves the selection of an appropriate family of stochastic models, an evaluation of their compatibility with the available data (goodness of fit) and the subsequent estimation of or conduction of tests of hypotheses about some components of the chosen family of models. Such models may have different levels of complexity and depend on assumptions with different degrees of restrictiveness, as illustrated by the following examples.

Example 1 Suppose that the proficiency of students in some subject (e.g., mathematics) is measured by the outcome in a given test and that we are interested in comparing the performance of males and females based on data obtained from independent random samples. We may assume that the outcome corresponds to a score Y for which the underlying distribution function F is normal with common variance σ^2 and mean μ_1 for males or μ_2 for females; the data correspond to the scores $Y_{i1}, \dots, Y_{in_i}, i = 1, 2$, obtained from the n_1 male and n_2 female students in the sample. Alternatively, we may consider the outcome to be the classification of the test result for each student as failed, acceptable, good, or excellent so that the data correspond to the frequencies $n_{ik}, i = 1, 2, k = 1, 2, 3, 4$ of male and female students classified in each category. Here, a product multinomial model with parameters π_{ik} denoting the probabilities of classification in the k th response category for students in the i th group, is appropriate.

Example 2 In cases where the test is composed of L dichotomous or polytomous questions or items sampled from a large item population, 'item response theory' models are often appropriate to measure the proficiency of students (Hambleton *et al.*, 1991). In this context, the probability that a student answers an item correctly is modeled as a function of his/her proficiency (a latent trace) and of some characteristics of the item. For example, the one-parameter logistic model is

$$\pi_{lj} = \pi_{lj}(\theta_j, b_l) = P(U_{lj} = 1 | \theta_j, b_l) = \frac{1}{1 + e^{-(\theta_j - b_l)}}$$

where π_{lj} is the conditional probability of a correct answer to item l given by student j , U_{lj} is a Bernoulli random variable with probability of success π_{lj} , θ_j is the proficiency of student j , and b_l is the location (or difficulty) parameter for item l . The data consist of the values of $U_{lj}, j = 1, \dots, n, l = 1, \dots, L$ corresponding to the responses of all sampled students to all sampled items.

In Example 1, it is well known that the Student t -statistic

$$t = (\bar{Y}_1 - \bar{Y}_2) / (S \sqrt{1/n_1 + 1/n_2})$$

where $\bar{Y}_i = n_i^{-1} \sum_{j=1}^{n_i} Y_{ij}, i = 1, 2$, respectively, denote the sample mean score for males and females and $S^2 = [n_1 + n_2 - 2]^{-1} \sum_{i=1}^2 \sum_{j=1}^{n_i} (Y_{ij} - \bar{Y}_i)^2$ represents the sample variance, follows an exact t -distribution with $n_1 + n_2 - 2$ degrees of freedom under the hypothesis that $\mu_1 = \mu_2$ and thus, may be employed to construct an exact test of such hypothesis. In the second setup, to test for the equality of the response distributions of males and females, we usually employ Pearson's χ^2 -statistic $Q = \sum_{i=1}^2 \sum_{k=1}^4 (n_{ik} - e_{ik})^2 / e_{ik}$, where $e_{ik} = (n_{i.} n_{.k}) / n, n_{i.} = \sum_{k=1}^4 n_{ik}$ and $n_{.k} = \sum_{i=1}^2 n_{ik}$. Unfortunately, the exact distribution of Q is difficult to specify, especially when the sample sizes are large, and therefore, we must rely on an approximate χ^2 distribution to construct the test.

In Example 2, assuming that the answers of student j to the L items, conditionally on his/her proficiency, are independent, θ_j and b_l can be estimated by maximum likelihood methods, that is, by maximizing the log-likelihood function

$$l(\theta, b) = \sum_{j=1}^n \sum_{l=1}^L \{u_{lj} \log[\pi_{lj}(\theta_j, b_l)] + (1 - u_{lj}) \log[1 - \pi_{lj}(\theta_j, b_l)]\}$$

where θ and b are vectors whose elements are the proficiency and item parameters, respectively, and u_{lj} denotes the realization of U_{lj} . Here, the estimating equations

$$\sum_{j=1}^n [u_{lj} - \pi_{lj}(\hat{\theta}_j, \hat{b}_l)] = 0 \text{ and } \sum_{l=1}^L [u_{lj} - \pi_{lj}(\hat{\theta}_j, \hat{b}_l)] = 0$$

do not have a closed form solution (Baker and Kim, 2004), and the maximum likelihood estimators $\hat{\theta}_j$ and \hat{b}_l must be

obtained by numerical algorithms. Therefore, the quest for approximations to the distributions of such estimators is even more pressing.

With the exception of some simple cases, the exact statistical properties of many useful estimators and test statistics are not obtainable for many models of practical interest. Therefore, the methods for approximating the probability distributions (or some appropriate summary measures) of such statistics are of special concern. The main tools for such approximations are based on statistical properties derived by letting the sample size n be indefinitely large and are investigated under the denomination of asymptotic statistical theory. Since, in practice, the asymptotic results generate methods that must be applied to samples of finite (although large) sizes, they are also known as large-sample methods and, therefore, must be considered as approximations. Nevertheless, they are associated with the following advantages:

- They allow for some flexibility in the selection of models since large-sample properties of estimators and test statistics are usually less dependent on the particular functional form of the underlying distribution than their exact (small-sample) counterparts, and thus, are relatively robust against departures from some assumed model.
- They allow for some relaxation of the assumptions of independence and identical distribution of the sample elements, usually required by exact inferential procedures.
- They generally produce simple and well-studied limiting distributions such as the normal, χ^2 , Weibull, etc.

It is quite natural to expect that as the sample size increases, an estimator should be closer to the parameter it is set to estimate; this property is known as consistency and is intimately related to the concept of stochastic convergence of random variables. Similarly, a test statistic should be able to detect false null hypotheses with increasing confidence when the sample size becomes large. A second natural requirement for large-sample procedures is that the corresponding exact sampling distribution can be adequately approximated by a simpler one, such as the normal or χ^2 distribution, for which tables or computational algorithms are available. This is known as convergence in distribution or weak convergence and constitutes the basis of some important results known as central limit theorems. Third, in a given setup, there are usually many competing statistics satisfying the requirements of consistency and convergence in distribution. In choosing an appropriate one within such a class, we seek for optimality in some sense, such as minimum variance or minimum risk with respect to suitable loss functions in estimation problems, and this motivates the concepts of asymptotic efficiency. Similarly, in testing problems, large sample optimality properties are defined

in terms of alternative hypotheses that become closer to the null hypothesis as the sample size increases.

In this context, we consider the two basic forms of stochastic approximation useful for large samples; the first concerns the approximation of a parameter or possibly a random variable by a sequence of statistics, and the second is related to the approximation of a sequence of distribution functions by another distribution function with known properties.

Stochastic Convergence

We say that a sequence $\{T_n\}$ of real numbers converges to a limit T as n becomes indefinitely large, if for every positive ε , there exists a positive integer n_0 , possibly depending on ε , such that (Apostol, 1974)

$$|T_n - T| < \varepsilon \text{ for } n \geq n_0 \quad [1]$$

This may be equivalently expressed as

$$\sup_{N \geq n} |T_N - T| < \varepsilon \text{ for } n \geq n_0 \quad [2]$$

In dealing with a sequence $\{T_n\}$ of random elements (statistics), we note that no matter how large an n is chosen, the inequality $|T_n - T| < \varepsilon$ may not hold always when n is sufficiently large but may do so with probability arbitrarily close to 1. Furthermore, in the stochastic context, [1] and [2] are not equivalent and the difference in the probabilities of these two sets of events leads to the concepts of convergence in probability, and almost sure convergence, which essentially address different degrees of stochastic approximation. The latter is stronger and, in general, more stringent conditions are required for its validity. With a similar spirit, we may consider the concepts of convergence in the r th mean and complete convergence (Sen *et al.*, 2010). In practice, these concepts are usually employed to show that certain sequences of statistics, such as maximum likelihood or least-squares estimators, are consistent.

A second form of approximation refers to convergence in distribution or weak convergence. Here, we are not concerned with the convergence of the actual sequence of statistics $\{T_n\}$ to some constant or random variable T , but with the convergence of the corresponding distribution functions $\{G_n\}$ to some specific distribution function F . Thus, we say that the sequence of statistics $\{T_n\}$ converges in distribution (or weakly) to T if, for every given $\varepsilon > 0$, there exists an integer n_0 , possibly depending on ε , such that at every point of continuity (x) of F

$$|G_n(x) - F(x)| < \varepsilon, \text{ for } n \geq n_0$$

Although this mode of convergence is the weakest among those mentioned so far, it is very important for statistical applications, since the related limiting distribution function F may generally be employed in the construction of

approximate confidence intervals for and significance tests about the parameters of interest.

Classical applications of convergence results are focused on statistics that may be expressed as sums of functions of independent random variables as the sample means \bar{Y}_i in Example 1. The most important results on the convergence in probability or almost sure convergence of such statistics to the population parameters, are known as laws of large numbers (LLNs). As an example, the Khintchine weak LLN states that the sample mean (\bar{Y}_i) converges in probability to the (finite) population mean (μ_i), provided that the sample elements are independent and identically distributed. Essentially, this means that the probability that \bar{Y}_i differs from μ_i by less than a specified (small) constant can be made arbitrarily closer to 1 by increasing the sample size. The Khintchine strong LLN shows that statistics like \bar{Y}_i converge almost surely to μ_i under the same conditions. Similar results are available even if the underlying random variables are not identically distributed; in general, the price to pay is to require the existence of moments of higher order. This is the case with the Markov weak LLN or with the Kolmogorov strong LLN. By choice of an appropriate norm, we may also extend the results to vector-valued random variables (Sen *et al.*, 2010).

The proofs of such results generally rely on some probability inequalities, the most simple being the well-known Chebyshev inequality: given a sequence $\{T_n\}$ of random variables with mean μ and variance σ_n^2 , it follows that for all $n \geq 1$ and all real numbers t ,

$$P(|T_n - \mu| < t) \geq 1 - \sigma_n^2/t^2$$

Then, we conclude that whenever σ_n^2 converges to 0, T_n converges in probability to μ . To obtain stronger results, we need sharper inequalities such as the Bernstein or Hoeffding inequalities, for example. Although these inequalities were originally developed under the assumption that the underlying random variables are independent, they may be extended to more general cases provided some martingale-type structure (Chow and Teicher, 1978) can be imposed on their dependence pattern. Likelihood ratio test statistics, U -statistics, or empirical distribution functions, have such properties (Sen *et al.*, 2010).

Asymptotic Distributions

The main result on this topic, known as the central limit theorem (CLT), essentially demonstrates that statistics expressed as sums of the underlying random variables, conveniently standardized are asymptotically normally distributed, that is, converge weakly to the normal distribution. The CLT may be proved under different assumptions on the moments and on the dependence structure of

the underlying random variables. The most simple CLT states that the (sampling) distribution of the sample mean of independent and identically distributed random variables with mean μ and finite variance σ^2 may be approximated by a normal distribution with the same mean μ and variance σ^2/n . Although the limiting distribution is continuous, the underlying distribution may even be discrete. An interesting special case occurs when the underlying variable Y has the Bernoulli distribution, with probability of success π . Here, the expected value and the variance of Y are π and $\pi(1 - \pi)$, respectively, and the sample mean p is the proportion of sample elements for which $Y = 1$. It follows that the large-sample distribution of p may be approximated by a $N[\pi, \pi(1 - \pi)/n]$ distribution. This result is known as the De Moivre–Laplace CLT.

Weak convergence results are also available for independent, but not identically distributed (e.g., with different means and variances) underlying random variables, provided some (relatively mild) assumptions hold for their moments. The Liapounov CLT and the Lindeberg–Feller CLT are useful examples. Further extensions cover cases of dependent random underlying variables; in particular, the Hájek–Sidak CLT is extremely useful in regression analysis, where, as the sample size increases, the response variables form a triangular array in which for each row (i.e., for given n), they are independent, but this is not true among rows (i.e., for different values of n). Extensions to cover cases where the underlying random variables have more sophisticated (e.g., martingale-type) dependence structures have been considered by Dvoretzky (1971) among others.

The Slutsky theorem is a handy tool to prove weak convergence of statistics that may be expressed as the sum, product, or ratio of two terms, the first known to converge weakly to some distribution, and the second known to converge in probability to some constant. As an example, consider independent and identically distributed random variables Y_1, \dots, Y_n with mean μ and variance σ^2 . Since the corresponding sample standard deviation S converges in probability to σ and the distribution of \bar{Y} may be approximated by a $N(\mu, \sigma^2/n)$ distribution, we may apply Slutsky's theorem to show that the large-sample distribution of $\sqrt{n}\bar{Y}/S = (\sqrt{n}\bar{Y}/\sigma) \times (\sigma/S)$ may be approximated by a $N(\mu, 1)$ distribution. This allows us to construct approximate confidence intervals for and tests of hypotheses about μ based on the standard normal distribution. A similar approach may be employed to the Bernoulli example by noting that p is a consistent estimator of π .

An important application of Slutsky's theorem relates to statistics that can be decomposed as a sum of terms for which some CLT holds plus a term that converges in probability to 0. Assume, for example, that the variables Y_i have a finite fourth central moment γ and write the sample variance as

$$S^2 = [n/(n-1)] \left\{ n^{-1} \sum_{i=1}^n [(Y_i - \mu)^2 - \sigma^2/n] + \left[\sigma^2 - \sum_{i=1}^n (\bar{Y} - \mu)^2 \right] \right\}.$$

Since the first term within the $\{\}$ brackets is known to converge weakly to a normal distribution by the CLT and the second term converges in probability to 0, we conclude that the distribution of S^2 may be approximated by a $N(\sigma^2, \gamma/n)$ distribution. This is the basis of the projection results suggested by Hoeffding (1948) and extensively explored by Jurečková and Sen (1996) to obtain large-sample properties of U -statistics as well as of more general classes of estimators.

A convenient technique to obtain the asymptotic distributions of many (smooth) functions of asymptotically normal statistics is the Delta-method: if g is a differentiable function of a statistic T_n whose distribution may be approximated (for large samples) by a $N(\mu, \tau^2)$ distribution, then the distribution of the statistic $g(T_n)$ may be approximated by a $N\{g(\mu), [g'(\mu)]^2 \tau^2\}$ distribution, where $g'(\mu)$ denotes the first derivative of g computed at μ . In the context of Example 1, we may be interested in estimating the odds of a failed versus pass response, that is, $\pi_{i1}/(1 - \pi_{i1})$ for the students in the i th group. A straightforward application of the CLT may be used to show that the estimator of π_{i1} , namely, n_{i1}/n_i , follows an approximate $N[\pi_{i1}, \pi_{i1}(1 - \pi_{i1})/n_i]$ distribution. Taking $g(x) = x/(1 - x)$, we may use the Delta-method to show that the distribution of the sample odds $n_{i1}/(n_i - n_{i1})$ may be approximated by a $N\{\pi_{i1}/(1 - \pi_{i1}), \pi_{i1}/[n_i(1 - \pi_{i1})^3]\}$ distribution. This type of result has further applications in variance-stabilizing transformations used in cases (as the above example) where the variance of the original statistic depends on the parameter it is set to estimate.

These concepts and results may also be extended to the multivariate case; in particular, consideration must be given to the Cramér–Wold device, which is a useful process of reduction of multivariate problems to their univariate counterparts. In essence, it states that the asymptotic distribution of the former may be obtained by showing that the asymptotic distribution of every linear combination of the multivariate statistic under investigation may be approximated by a normal distribution.

For some important cases, such as the Pearson χ^2 -statistic, or more general quadratic forms $Q = Q(\boldsymbol{\mu}) = (\mathbf{Y} - \boldsymbol{\mu})' \mathbf{A} (\mathbf{Y} - \boldsymbol{\mu})$ where \mathbf{Y} is a p -dimensional random vector with mean vector $\boldsymbol{\mu}$ and covariance matrix \mathbf{V} and \mathbf{A} is a p -dimensional square matrix of full rank, the (multivariate) Delta-method may not be employed because the derivative of Q computed at $\boldsymbol{\mu}$ is null. If \mathbf{A} converges to an inverse of \mathbf{V} , a useful result known as the Cochran theorem states that the distribution of Q may be approximated by a χ^2 instead of a normal distribution. In fact, the theorem holds even if \mathbf{A} is not of full rank, but converges

to a generalized inverse of \mathbf{V} . This is important for applications in categorical data.

The CLT also does not hold for extreme order statistics such as the sample minimum or maximum; depending on some regularity conditions on the underlying random variables, the distribution of such statistics, conveniently normalized, may be approximated by one of the three types of distributions, namely, the extreme value distributions of the first, second, or third type, which, in this context, are the only possible limiting distributions as shown by Gnedenko (1943).

Given that weak convergence has been established, a question of interest is whether the moments (e.g., mean and variance) of the statistics under investigation converge to the moments of the limiting distribution. Although the answer is negative in general, an important theorem, due to Cramér, indicates conditions under which the result is true (Sen *et al.*, 2010).

For most practical purposes, the specification of an approximate distribution must be complemented with some discussion on the corresponding rates of convergence. In this direction, a bound on the error of approximation of the CLT is provided by the Berry–Esséen theorem; alternatively, such an evaluation may be carried out via Gram–Charlier or Edgeworth expansions (Cramér, 1946). Although this second approach might offer a better insight into the problem than that provided by the former, it requires the knowledge of the moments of the parent distribution and, thus, is less useful in practical applications.

Asymptotic Properties of Estimators and Test Statistics

The convergence of an estimator (in any of the modes described previously) to the parameter being estimated, is certainly desirable and, in general, holds under rather mild regularity conditions often satisfied in practice. A related, but stronger concept, frequently employed in consistency proofs, is that of asymptotic unbiasedness: a sequence $\{T_n\}$ of estimators is asymptotically unbiased if the corresponding expected values converge to the parameter being estimated as n increases indefinitely. In practice, however, such properties are of limited value if not coupled with some form of convergence in distribution. Fortunately, it is possible to obtain such asymptotic distributions for a large class of estimators. In particular, the large-sample distribution of maximum likelihood estimators may be approximated by a normal distribution with variance given by the inverse of the Fisher information, provided a rather mild compactness condition on the second derivative of the log-likelihood is satisfied (Sen *et al.*, 2010). This is generally true for estimators derived

under the exponential family of densities of the underlying random variables. Similar results are also available for other classes of parametric (e.g., robust estimators or more generally, M -estimators) or nonparametric estimators (e.g., those based on U - and V -statistics). Here, however, as shown in Jurečková and Sen (1996), more delicate assumptions are required.

Even if we restrict ourselves to the class of asymptotically normal estimators, we still need some further criteria in order to choose the best candidate; among them lies the concept of asymptotic relative efficiency (ARE), which, in the case of asymptotically normal estimators, corresponds to the ratio of the variances of the approximate distributions. In connection with such ideas, the concept of (absolutely) efficient estimators may be developed with a similar spirit to that of the Cramér–Rao–Fréchet inequality for finite samples; such estimators are termed best asymptotically normal (BAN), and for practical purposes, estimators having this property may be used interchangeably. Note that in general, the asymptotic relative efficiency of two estimators may not coincide with the Fisher asymptotic efficiency, defined as the ratio between the limit of the variance of the estimator (conveniently standardized) and the Cramér–Rao–Fréchet lower bound (Sen *et al.*, 2010).

Large-sample properties of test statistics derived by Wald, score, and likelihood ratio methods may also be obtained along the same lines. Comparing the large-sample efficiency of tests, however, is slightly more complicated, since for fixed alternative hypotheses, for example, $H_A: \mu = \mu_1$ where μ_1 is a constant, the power of such tests converge to 1 as the sample size increases. Therefore, we must restrict ourselves to local Pitman-type alternatives, for example, $H_A: \mu_n = \mu_0 + \Delta/\sqrt{n}$, where μ_0 and Δ are constants, which, in some sense, get closer to the null hypothesis $H_0: \mu = \mu_0$ as the sample size increases; this allows comparisons via the noncentrality parameters of the approximate distributions. Under this approach, we may show that Wald, score, and likelihood ratio methods generate (large-sample) equivalent and locally the most powerful tests.

Extensions to Regression and Categorical Data Models

Linear regression and related models pose special problems, since the underlying random variables are not identically distributed, and in many cases, the exact functional form of their distributions is not completely specified. Least-squares methods are attractive under these conditions, since they may be employed in a rather general setup. In this context, the Hájek–Šidak CLT specifies sufficient conditions on the explanatory variables such that the distributions of the estimators of the regression parameters may be approximated by normal distributions.

As an illustration, consider the simple linear regression model

$$y_i = \alpha + \beta x_i + e_i, \quad i = 1, \dots, n$$

where y_i and x_i represent observations of the response and explanatory variables, respectively, α and β are the parameters of interest, and the e_i correspond to uncorrelated random errors with mean 0 and variance σ^2 . The least-squares estimators of β and α are, respectively, $\hat{\beta} = \sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y}) / \sum_{i=1}^n (x_i - \bar{x})^2$ and $\hat{\alpha} = \bar{y} - \hat{\beta}\bar{x}$, where \bar{x} and \bar{y} correspond to the sample means of the explanatory and response variables. Irrespective of the form of the underlying distribution of e_i , we may use standard results to show that $\hat{\alpha}$ and $\hat{\beta}$ are unbiased and have variances given by $\sigma^2 [\sum_{i=1}^n x_i^2 / \sum_{i=1}^n (x_i - \bar{x})^2]$ and $\sigma^2 [\sum_{i=1}^n (x_i - \bar{x})^2]^{-1}$, respectively. Furthermore, the covariance between $\hat{\alpha}$ and $\hat{\beta}$ is $-\sigma^2 \bar{x} / \sum_{i=1}^n (x_i - \bar{x})^2$. When the underlying distribution of e_i is normal, we may use standard results to show that $\hat{\alpha}$ and $\hat{\beta}$ follow a bivariate normal distribution. If $\max_{1 \leq i \leq n} (x_i - \bar{x})^2 / \sum_{i=1}^n (x_i - \bar{x})^2$ converges to 0 (Noether's condition) and both \bar{x} and $n^{-1} \sum_{i=1}^n (x_i - \bar{x})^2$ converge to finite constants as n increases indefinitely, we may use the Hájek–Šidak CLT to conclude that the same bivariate normal distribution specified above serves as an approximation of the true distribution of $\hat{\alpha}$ and $\hat{\beta}$, whatever the form of the distribution of e_i , provided that n is sufficiently large.

The results may also be generalized to cover alternative estimators obtained by means of generalized and weighted least-squares procedures as well as via robust M -estimation procedures. They may also be extended to generalized linear and nonlinear models.

Applications to categorical data pose additional problems, since many nonlinear models are attractive for their analysis. Although maximum likelihood estimators have optimal large-sample properties, they often require laborious computation because of the natural restrictions involving the parameters of the underlying multinomial distributions. In such cases, they are usually replaced by competitors such as minimum chi-squared, modified minimum chi-squared, or generalized least-squares estimators. Since all these methods generate BAN estimators, their large-sample properties are equivalent (Paulino and Singer, 2006) and the choice among them may rely on computational considerations.

Extensions to Empirical Distribution Functions and Order Statistics

Empirical distribution functions and order statistics have important applications in nonparametric regression models, resampling methods such as the jackknife and bootstrap, sequential testing, as well as in survival and

reliability analyses. In particular, they serve as the basis for the well-known goodness-of-fit Kolmogorov–Smirnov and Cramér–von Mises statistics and for L - and R -estimators such as trimmed or Winsorized means. Given the sample observations Y_1, \dots, Y_n assumed to follow some distribution function F , the empirical distribution function computed at a given real number y is

$$F_n(y) = n^{-1} \sum_{i=1}^n I(Y_i \leq y)$$

where $I(Y_i \leq y)$ is an indicator function assuming the value 1 if $Y_i \leq y$ and 0 otherwise. It is intimately related to the order statistics, $Y_{n:1} \leq Y_{n:2} \leq \dots \leq Y_{n:n}$ where $Y_{n:1}$ is the smallest among Y_1, \dots, Y_n , $Y_{n:2}$ is the second smallest, and so on. For each fixed sample, F_n is a distribution function when considered as a function of y . For every fixed y , when considered as a function of Y_1, \dots, Y_n , $F_n(y)$ is a random variable; in this context, since the $I(Y_i \leq y)$, $i = 1, \dots, n$, are independent and identically distributed zero-one valued random variables, we may apply the CLT to conclude that for each fixed y , the distribution of $F_n(y)$ may be approximated by an $N\{F(y), F(y)[1 - F(y)]/n\}$ distribution, provided that n is sufficiently large. To extend these results to the function F_n computed at all real values y , more sophisticated methods are needed as suggested in Jurečková and Sen (1996) among others.

Conclusion

When the sample size is small, properties of estimators and test statistics required for inferential purposes may be either hard to derive or based on assumptions that are difficult to verify in practical applications. Large-sample methods developed under mild assumptions, usually acceptable for most practical problems, provide approximations for such properties and generally lead to standard inferential procedures, such as confidence intervals based on the normal distribution or χ^2 -distributed test statistics. Although the underlying theory lies on asymptotic (i.e., sample sizes tending to infinity) arguments, the resulting approximate procedures may be satisfactorily employed in cases where the sample size is moderate or even small.

Latent Class Models

J K Vermunt, Tilburg University, Tilburg, The Netherlands

© 2010 Elsevier Ltd. All rights reserved.

Introduction

A statistical model can be called a latent class (LC) or mixture model if it assumes that some of its parameters differ across unobserved subgroups, LCs, or mixture components. This rather general idea has several seemingly unrelated applications, the most important of which are clustering, scaling, density estimation, and random-effects modeling. It should be noted that in applied fields, the terms LC model and mixture model are often used interchangeably, which is also what is done here. In the more technical statistical literature on mixture modeling, the term LC analysis is reserved for a specific type of mixture model, that is, a mixture model for a set of categorical items (for the classical LC model).

LC analysis was introduced in 1950 by Lazarsfeld as a tool for building typologies (or clustering) based on dichotomous observed variables (Lazarsfeld, 1950). More than 20 years later, Goodman (1974) made this model applicable in practice by developing an algorithm for obtaining maximum-likelihood estimates of the model parameters, as well as proposed extensions for polytomous manifest variables and did important work on the issue of model identification. Many important extensions of this classical LC model have been proposed since then, such as models containing explanatory variables (Dayton and Macready, 1988), models that relax the local-independence assumption (Hagenaars, 1988), constrained models similar to item response theory (IRT) models (Lindsay *et al.*, 1991; Heinen, 1996), models with multiple latent variables (Magidson and Vermunt, 2001), models for longitudinal data (Van de Pol and Langeheine, 1990), and models for multilevel data (Vermunt, 2003).

Whereas this classical LC model and its extensions are conceived primarily as a clustering and scaling tool for categorical data analysis, LC and finite-mixture models can be useful in several other areas as well. One of these is as a probabilistic cluster-analysis tool for continuous observed variables, an approach that offers many advantages over traditional cluster techniques such as K-means clustering (Wolfe, 1970; McLachlan and Peel, 2000; Vermunt and Magidson, 2002). Another application area is dealing with unobserved heterogeneity, as happens in mixture regression analysis of multilevel or repeated-measurement data (Wedel and DeSarbo, 1994; Vermunt and Van Dijk, 2001).

The remainder of this article is organized as follows. After introducing the simplest type of LC models, various

restricted LC models as well as models with explanatory variables are discussed. Next, an overview of other types of LC and mixture models, which includes various recently proposed extensions, is presented. In the end, attention is paid to parameter estimation, model selection, and software.

Simple LC and Mixture Models

LC analysis is typically used as a tool for analyzing multivariate response data; that is, data consisting of several dependent variables, response variables, or items. We denote the response of subject i on dependent variable j by y_{ij} , and the number of dependent variables by J . The full-response vector of a subject is denoted by \mathbf{y}_i . To make things more concrete, **Table 1** presents a small illustrative data set consisting of three dichotomous responses, y_{i1} , y_{i2} , and y_{i3} (0 = incorrect; 1 = correct). This is a subset of items from a mathematics test administered to 2156 children. The frequency column contains the observed frequency count for each of the eight possible answer patterns.

In addition to the J observed dependent variables, an LC model contains a discrete latent variable. We denote a subject's unobserved score on this latent variable by v_i , the number of LCs by C , and a particular class by c , where $c = 1, 2, \dots, C$. The aim of an LC analysis of the data set in **Table 1** could be to classify pupils into two groups, masters and nonmasters, which differ with respect to the probability of answering the test items correctly. The results obtained with a two-class model will be used to illustrate the various components of an LC model.

LC analysis defines a model for $f(\mathbf{y}_i)$, the probability density of the multivariate response vector \mathbf{y}_i . In the above example, this is the probability of answering the items according to one of the eight possible response patterns, for example, of answering the first two items correctly and the last one incorrectly, which as can be seen in **Table 1** equals 0.161 for the estimated two-class model. The assumption underlying any type of LC or mixture model is that the density $f(\mathbf{y}_i)$ is a weighted average (or mixture) of the C class-specific densities $f(\mathbf{y}_i|v_i = c)$. This is expressed mathematically as follows:

$$f(\mathbf{y}_i) = \sum_{c=1}^C P(v_i = c) f(\mathbf{y}_i|v_i = c). \quad [1]$$

Here, $P(v_i = c)$ denotes the probability that a subject belongs to LC c . For our small empirical example, the estimates of these (prior) class membership probabilities

Table 1 Small data set with three dichotomous responses

y_{i1}	y_{i2}	y_{i3}	Frequency	$f(y_i v_i = 1)$	$f(y_i v_i = 2)$	$f(y_i)$	$f(v_i = 1 y_i)$	$f(v_i = 2 y_i)$	Modal
0	0	0	239	0.004	0.272	0.111	0.020	0.980	2
0	0	1	101	0.010	0.102	0.047	0.128	0.872	2
0	1	0	283	0.038	0.271	0.131	0.175	0.825	2
0	1	1	222	0.104	0.102	0.103	0.605	0.395	1
1	0	0	105	0.020	0.092	0.049	0.248	0.753	2
1	0	1	100	0.054	0.035	0.046	0.703	0.297	1
1	1	0	348	0.208	0.091	0.161	0.774	0.226	1
1	1	1	758	0.562	0.034	0.352	0.961	0.039	1

are 0.601 and 0.399 for classes 1 and 2, respectively (see **Table 2**). The assumed mechanism by eqn [1] is that each individual belongs to one of C exhaustive and mutually exclusive classes with probability $P(v_i = c)$ and that given membership of LC c one provides responses according to the probability density associated to this class. **Table 1** shows the estimated values of $f(y_i|v_i = 1)$ and $f(y_i|v_i = 2)$ for our data sets. As can be seen, LC 1 has higher probabilities for the response patterns with 2 or 3 correctly answered items, whereas class 2 has higher probabilities for the response patterns with 0 or 1 item correct.

The classical LC model combines the assumption of eqn [1] shared by all mixture models with the assumption of local independence. Local independence means that the \mathcal{J} responses are mutually independent given a subject's class membership. It can be expressed as follows:

$$f(y_i|v_i = c) = \prod_{j=1}^{\mathcal{J}} f(y_{ij}|v_i = c). \quad [2]$$

Independence implies that the joint density $f(y_i|v_i = c)$ is obtained as a product of the \mathcal{J} item-specific densities $f(y_{ij}|v_i = c)$. In our example $f(y_{ij} = 1|v_i = c)$ is the class-specific probability of giving a correct answer to item j . As reported in **Table 2**, for a subject belonging to the first LC, these equal 0.844, 0.912, and 0.730 for items 1, 2, and 3, respectively. The local independence assumption implies, for example, that the probability of answering the first two items correctly and the last one incorrectly for someone in LC one equals $0.844 \times 0.912 \times (1 - 0.730) = 0.208$. Note that the local independence assumption is also used in other types of latent variables models, such as in factor analysis and IRT modeling, and is thus not specific for LC analysis.

Combining the two basic eqns [1] and [2] yields the following model for $f(y_i)$:

$$f(y_i) = \sum_{c=1}^C P(v_i = c) \prod_{j=1}^{\mathcal{J}} f(y_{ij}|v_i = c). \quad [3]$$

To complete the model specification, we need to define the form of the conditional densities $f(y_{ij}|v_i = c)$. In the classical LC model for categorical items, these are multinomial probability densities; that is,

Table 2 Parameters (class proportions and probability of a correct answer) obtained with two-class model for data in **Table 1**

	$c = 1$	$c = 2$
$P(v_i = c)$	0.601	0.399
$\pi_{11c} = P(y_{i1} = 1 v_i = c)$	0.844	0.252
$\pi_{21c} = P(y_{i2} = 1 v_i = c)$	0.912	0.499
$\pi_{31c} = P(y_{i3} = 1 v_i = c)$	0.730	0.273

$$f(y_{ij}|v_i = c) = \prod_{r=0}^{R_j-1} \pi_{jrc}^{y_{ijr}^*},$$

where R_j is the number of categories of item j , $0 \leq y_{ij} \leq R_j - 1$, and $y_{ijr}^* = 1$ if $y_{ij} = r$ and 0 otherwise. Note this is a slightly complicated, but mathematically elegant, way to express that someone in LC c has a probability equal to $\pi_{jrc} = P(y_{ij} = r|v_i = c)$ of giving response r to item j . In the special case of a dichotomous response, the multinomial distribution reduces to the Bernoulli distribution with success probability $\pi_{jc} = \pi_{j1c} = P(y_{ij} = 1|v_i = c)$. **Table 2** presents these probabilities for our small example.

It is important to note that LC models cannot only be used with categorical responses, but also with continuous responses and counts. The density $f(y_{ij}|v_i = c)$ could be a binomial, Poisson, or negative binomial distribution for counts, and a normal or gamma distribution for continuous responses. The mixture model for continuous response variables is sometimes referred to as the latent profile model. The parameters of this model are the class proportions and class-specific item means and variances (μ_{jc} and σ_{jc}^2).

By comparing the \mathcal{J} sets of item parameters across classes, one can name the classes. The parameter estimates presented in **Table 2** show that the first class can be named the masters because pupils belonging to that class have much higher probabilities of answering the test items correctly than pupils belonging to the second non-masters class.

Similar to cluster analysis, one of the purposes of LC analysis might be to assign individuals to LCs.

The probability of belonging to LC c given responses \mathbf{y}_i – often referred to as posterior membership probability – can be obtained by the Bayes rule:

$$P(v_i = c | \mathbf{y}_i) = \frac{P(v_i = c) f(\mathbf{y}_i | v_i = c)}{f(\mathbf{y}_i)}. \quad [4]$$

Table 1 reports $P(v_i = c | \mathbf{y}_i)$ for each answer pattern. For example, $P(v_i = 1 | \mathbf{y}_i)$ equals 0.774 for the (1,1,0) pattern, which is obtained as $0.601 \times 0.208 / 0.161$. The most common classification rule is modal assignment, which amounts to assigning each individual to the LC with the highest $f(v_i = c | \mathbf{y}_i)$. The last column of **Table 1** reporting the modal assignments shows that pupils with at least two correct answers are assigned to class 1 and the others to class 2.

In the introduction, we stated that mixture models are statistical models in which parameters are assumed to differ across LCs. But what is the statistical model used in the simple LC models discussed so far? It is the independence model: we assume responses to be independent, with different parameter values for each class. Depending on the scale type of the response variables, these parameters are Bernoulli probabilities, multinomial probabilities, normal means and variances, Poisson rates, etc.

Generalized Linear Models for Item Probabilities/Mean

Haberman (1979) showed that the LC model for categorical response variables can also be specified as a log-linear model for an expanded table, including the latent variable v_i as an additional dimension. Using such a log-linear specification is equivalent to parameterizing the response probability for item j as follows:

$$\log\left(\frac{\pi_{jrc}}{\pi_{j0c}}\right) = \log\left(\frac{P(\mathcal{Y}_{ij} = r | v_i = c)}{P(\mathcal{Y}_{ij} = 0 | v_i = c)}\right) = \alpha_{jr} + \beta_{jcr}, \quad [5]$$

for $1 \leq r \leq R_j - 1$; that is, as a multinomial logistic regression models with intercepts α_{jr} and slopes β_{jcr} (note that we use the first item category, $r = 0$, as baseline). One identification constraint needs to be imposed, for example, $\beta_{j1r} = 0$ (the parameters for class 1 are fixed to 0) or $\alpha_{jr} = 0$ (intercepts are fixed to 0).

For dichotomous responses and binomial counts, the regression model could be a binary logit or probit model, for Poisson counts a log-linear model, and for continuous responses a standard linear model. These are generalized linear models (GLMs) of the form

$$g[E(\mathcal{Y}_{ij} | v_i = c)] = \alpha_j + \beta_{jc}, \quad [6]$$

where $g[\cdot]$ is the link function transforming the expected value of \mathcal{Y}_{ij} to the linear term. For ordinal polytomous variables, one may use an ordinal regression model,

such as an adjacent-category or cumulative logit model. These are models that restrict the item response probabilities π_{jrc} .

Some Restricted Models for Categorical Items

Many interesting types of restricted LC models for categorical items have been proposed, which involve imposing (linear) constraints on either the conditional probabilities π_{jrc} or the logit coefficients of eqn [5]. One of these is the probabilistic Guttman scaling model for dichotomous responses, which is an LC model with $C = \mathcal{J} + 1$ classes, one for each possible total score. The idea is that apart from measurement error, class c should provide a negative answer to the $c - 1$ easiest items and a positive answer to the remaining $\mathcal{J} - (c - 1)$ items. The various types of probabilistic Guttman models differ in the constraints they impose on the measurement error. The simplest and most restricted model is the Proctor (1970) model. **Table 3** presents the parameter estimates obtained when fitting the Proctor model to the data set in **Table 1**. As can be seen, the probability of a correct response is either 0.833 or $0.167 = 1 - 0.833$. The measurement error – or the probability of giving a response which is not in agreement with the class – is estimated to be equal to 0.167. Whereas the Proctor model assumes that the measurement error is constant across items and classes, less-restricted models can be defined which allow the error probabilities to differ across items, classes, or both (see, e.g., Dayton, 1999). Note that these equality constraints on the error probabilities can also be defined using linear constraints on the logit parameters: $\alpha_{j1} = 0$ and $\beta_{j1c} = -\beta^*$ for $c \leq j$ and $\beta_{jc} = \beta^*$ otherwise.

Croon (1990) proposed a restricted LC model that similar to nonparametric IRT (Sijtsma and Molenaar, 2000) assumes monotonic item response functions; that is, $\pi_{j1c} \leq \pi_{j1,c+1}$, or, equivalently, $\beta_{j1c} \leq \beta_{j1,c+1}$. A more restricted version, in which not only classes but also items are ordered, is obtained by imposing the additional set of restriction $\pi_{j+11c} \leq \pi_{j1c}$; that is, by assuming double monotony. Vermunt (2001) has discussed various generalizations of these models.

Table 3 Parameters (class proportions and probability of a correct answer) obtained with proctor model for data in **Table 1**

	$c = 1$	$c = 2$	$c = 3$	$c = 4$
$P(v_i = c)$	0.160	0.155	0.126	0.559
$\pi_{21c} = P(\mathcal{Y}_{12} = 1 v_i = c)$	0.167	0.833	0.833	0.833
$\pi_{11c} = P(\mathcal{Y}_{11} = 1 v_i = c)$	0.167	0.167	0.833	0.833
$\pi_{31c} = P(\mathcal{Y}_{13} = 1 v_i = c)$	0.167	0.167	0.167	0.833

Various authors described the connection between restricted LC analysis and parametric IRT modeling (see, e.g., Heinen, 1996; Lindsay *et al.*, 1991); that is, IRT models with a discrete specification of the distribution of the underlying trait or ability can be defined as LC models with restrictions on the logistic parameters. The key restriction is $\beta_{jrc} = \beta_{jr}^* \cdot \theta_c$ for nominal items and $\beta_{jrc} = \beta_j^* \cdot r \cdot \theta_c$ for ordinal items, where θ_c are LC locations representing the C possible values of the discretized latent trait. These locations may be fixed *a priori*, for example, at $-2, -1, 0, 1$, and 2 in the case of $C = 5$, but may also be treated as free parameters to be estimated. Depending on whether the items are dichotomous, ordinal, or nominal, this yields a 2-parameter logistic, generalized partial credit, or nominal response model. Further restrictions involve equating β_j^* across items, yielding Rasch and partial credit models, and imposing across-category and across-item restrictions on α_{jr} parameters as in rating scale models for ordinal items.

Models with Explanatory Variables

The most important extension of the LC models discussed so far is the possibility to include explanatory variables affecting the responses (Wedel and DeSarbo, 1994) or the class memberships (Dayton and Macready, 1988). Denoting the vector with explanatory variables for subject i by \mathbf{x}_i , the LC model of interest can be formulated as follows:

$$f(\mathbf{y}_i | \mathbf{x}_i) = \sum_{c=1}^C P(v_i = c | \mathbf{x}_i) \prod_{j=1}^{j_i} f(y_{ij} | v_i = c, \mathbf{x}_{ij}). \quad [7]$$

The main difference compared to the model defined in eqn [3] is that now we have a model for $f(\mathbf{y}_i | \mathbf{x}_i)$ – the conditional density of \mathbf{y}_i given \mathbf{x}_i .

Similar to the regression models for the response variables introduced in eqns [5] and [6], one can define a mixture regression model with explanatory variables; that is,

$$g[E(y_{ij} | v_i = c, \mathbf{x}_{ij})] = \alpha_c + \sum_{p=1}^P \beta_{pc} x_{ijp}. \quad [8]$$

As before, y_{ij} may refer to the response on item j by pupil i , in which case the explanatory variables will consist of a design matrix defining the item parameters. However, the model in eqn [8] can also be used for many other purposes. In fact, it is a model for analyzing two-level data sets, where regression parameters are allowed to differ across LCs (of higher-level units). For example, y_{ij} could be the test score of pupil j belonging to school i , and \mathbf{x}_{ij} a set of pupil characteristics (e.g., intelligence quotient (IQ)). A mixture regression model would identify LCs of schools with different intercepts and different effects of child characteristics on the test scores.

Another possible application is in the analysis of longitudinal data, where j is a time point for subject i , and where vector \mathbf{x}_{ij} contains time variables. This yields a LC growth model in which subjects are grouped based on their developmental trajectories (Vermunt, 2007). A last possible application that can be mentioned is in experiments in which subjects are observed in multiple conditions, such as in conjoint studies. The mixture regression model can be used to group subjects based on their reactions on the experimental conditions. In fact, in each of these application types, the LC model is used as a random-coefficient model without parametric assumptions about the distribution of the random effects (Aitkin, 1999; Vermunt and Van Dijk, 2001).

As shown in eqn [7], an individual's class membership may also be predicted using covariates. This is achieved by defining a multinomial logistic regression model for $P(v_i = c | \mathbf{x}_i)$:

$$\log \frac{P(v_i = c | \mathbf{x}_i)}{P(v_i = 1 | \mathbf{x}_i)} = \gamma_{0c} + \sum_{q=1}^Q \gamma_{qc} x_{iq}.$$

Strongly related are multiple-group LC models. These can be defined using the grouping variable as a nominal explanatory in the model.

Extensions

The most common model-fitting strategy in LC analysis is to increase the number of classes until the local-independence assumption holds. This may, however, yield solutions which are difficult to interpret. One alternative approach is to relax the local-independence assumption by allowing for associations between particular item pairs. Hagenaars (1988) showed how to define LC models with local dependencies for categorical responses. With continuous responses, this is easily achieved using multivariate instead of univariate normal distributions for locally dependent items (see, e.g., McLachlan and Peel, 2000; Vermunt and Magidson, 2002).

Another alternative strategy involves increasing the number of discrete latent variables instead of the number of LCs, which is especially useful if the items measure several dimensions. This so-called discrete-factor modeling approach (Magidson and Vermunt, 2001) is a special case of the path-modeling approach for discrete latent variables developed by Hagenaars (1990) and Vermunt (1997). Many other interesting models can be defined within this framework, such as latent Markov models for the analysis of longitudinal data (Van de Pol and Langeheine, 1990) and LC models for cognitive diagnosis (De la Torre and Douglas, 2004).

Recently, models have been developed that contain both discrete and continuous latent variables. Examples of these are mixture factor models (Yung, 1997; McLachlan

and Peel, 2000), mixture structural equation models (Dolan and Van der Maas, 1997), and mixture IRT models (Rost, 1990).

Probably the most recent extension is the multilevel LC model (Vermunt, 2003). One of its variants is a model with discrete latent variables at multiple levels of a hierarchical structure: for example, children belong to LCs with different performances on a set of test items, and schools belong to LCs with different distributions of children across the child-level performance classes. Multilevel LC models can be used for the analysis of two-level multivariate and three-level univariate response data.

Maximum Likelihood Estimation

The parameters of LC models are typically estimated by means of maximum likelihood (ML). The log-likelihood function that is maximized is based on the probability densities defined in eqns [1–3]; that is,

$$\ln L = \sum_{i=1}^N \ln f(\mathbf{y}_i).$$

With categorical responses one will typically group the data and construct a frequency table as we did in **Table 1**. The log-likelihood function for grouped data equals

$$\ln L = \sum_{k=1}^K n_k \ln f(\mathbf{y}_k),$$

where k is a data pattern, K the number of different data patterns, and n_k the cell count corresponding to data pattern k . Notice that only nonzero observed cell entries contribute to the log-likelihood function, a feature that is exploited by several more efficient LC software packages that have been developed within the past few years.

One of the problems in the estimation of LC models for discrete y_{ij} is that model parameters may be nonidentified, even if the number of degrees of freedom – the number of independent cells in the J -way cross-tabulation minus the number of free parameters – is larger or equal to zero. Nonidentification means that different sets of parameter values yield the same maximum of the log-likelihood function or, worded differently, that there is no unique set of parameter estimates. The formal identification check is via the Jacobian matrix (matrix of first derivatives of $f(\mathbf{y}_i)$), which should be column full rank. Another option is to estimate the model of interest with different sets of starting values. Except for local solutions (see below), an identified model gives the same final estimates for each set of the starting values.

Although there are no general rules with respect to the identification of LC models, it is possible to provide certain minimal requirements and point to possible pitfalls. For an unrestricted LC analysis, one needs at least

three responses (y_{ij} 's) per individual, but if these are dichotomous, no more than two LCs can be identified. One has to watch out with four dichotomous response variables, in which case the unrestricted three-class model is not identified, even though it has a positive number of degrees of freedom. With five dichotomous items, however, even a five-class model is identified. Usually, it is possible to achieve identification by constraining certain model parameters.

A second problem associated with the estimation of LC models is the presence of local maxima. The log-likelihood function of an LC model is not always concave, which means that hill-climbing algorithms may converge to a different maximum depending on the starting values. Usually, we are looking for the global maximum. The best way to proceed is, therefore, to estimate the model with different sets of random starting values. Typically, several sets converge to the same highest log-likelihood value, which can then be assumed to be the ML solution. Some software packages have automated the use of multiple sets of random starting values to reduce the probability of getting a local solution.

Another problem in LC modeling is the occurrence of boundary solutions, which are probabilities equal to 0 (or 1) or logit parameters equal to minus (or plus) infinity. These may cause numerical problems in the estimation algorithms, occurrence of local solutions, and complications in the computation of standard errors and number of degrees of freedom of the goodness-of-fit tests. Boundary solutions can be prevented by imposing constraints or by taking into account other kinds of prior information on the model parameters.

The most popular methods for solving the ML estimation problem are the expectation–maximization (EM) and Newton–Raphson (NR) algorithms. EM is a very stable iterative method for ML estimation with incomplete data. NR is a faster procedure that, however, needs good starting values to converge. The latter method makes use of the matrix of second-order derivatives of the log-likelihood function, which is also needed for obtaining standard errors of the model parameters.

Model Selection Issues

The goodness-of-fit of LC models for categorical responses can be tested using Pearson and likelihood-ratio chi-squared tests. The latter is defined as

$$L^2 = 2 \sum_{k=1}^K n_k \ln \frac{n_k}{N \cdot f(\mathbf{y}_k)}.$$

As in log-linear analysis, the number of degrees of freedom (df) equals the number of cells in the frequency table minus 1, minus the number of independent parameters. In an unrestricted LC model,

$$df = \prod_{j=1}^J R_j - C \cdot \left[1 + \sum_{j=1}^J (R_j - 1) \right].$$

Although it is no problem to estimate LC models with 10, 20, or 50 indicators, in such cases, the frequency table may become very sparse and, as a result, asymptotic p -values can no longer be trusted. An elegant but somewhat time-consuming solution to this problem is to estimate the p -values by parametric bootstrapping. Another option is to assess model fit in lower order marginal tables (e.g., in the two-way marginal tables).

Even though models with C and $C + 1$ are nested, one cannot test them against each other using a standard likelihood-ratio test because it does not have an asymptotic chi-squared distribution. A way out to this problem is to approximate its sampling distribution using bootstrapping. But since this method is computationally demanding, usually alternative methods are required for comparing models with different numbers of classes. One popular method is the use of information criteria such as the Bayesian information criterion (BIC) and Akaike information criterion (AIC). Another more descriptive method is a measure for the proportion of total association accounted for by a C -class model, $[L^2(1) - L^2(C)]/L^2(1)$, where the L^2 value of the one-class (independence) model, $L^2(1)$, is used as a measure of total association in the J -way frequency table.

Usually, we are not only interested in goodness-of-fit but also in the performance of the modal classification rule (see eqn [4]). The estimated proportion of classification errors under modal classification equals

$$E = \sum_{i=1}^N \frac{1}{N} \{1 - \max[P(v_i = c | y_i)]\}.$$

This number can be compared to the proportion of classification errors based on the unconditional probabilities $P(v_i = c)$, yielding a reduction of errors measure

$$\lambda = 1 - \frac{E}{1 - \max[P(v_i = c)]}.$$

The closer this nominal R^2 -type measure is to 1, the better the classification performance of a model. Other types of classification error-reduction measures have been proposed based on entropy or qualitative variance.

Software

One of the first LC analysis programs, maximum likelihood latent structure analysis (MLLSA), made available by Clifford Clogg in 1977, was limited to a relatively small number of nominal variables. Today's programs can handle many more variables, as well as other scale types. For example, the LEM program (Vermunt, 1997) provides

a command language that can be used to specify a large variety of models for categorical data, including LC models. Mplus is a command-language-based structural-equation modeling package that implements many types of LC and mixture models. In addition, routines for the estimation of specific types of LC models are available as SAS, R, and Stata macros (see, e.g., Lanza *et al.*, 2007; Skrondal and Rabe-Hesketh, 2004).

Latent GOLD is a program that was especially developed for LC analysis, and which contains both an SPSS-like point and click-user interface and a syntax language. It implements all important types of LC models, such as models for response variables of different scale types, restricted LC models, models with predictors, models with local dependencies, models with multiple discrete latent variables, LC path models, LC Markov models, mixture factor analysis and IRT, and multilevel LC models, as well as features for dealing with partially missing data, for performing bootstrapping, and for dealing with complex samples.

Glossary

Bayesian – An approach to statistical inference in which parameters are treated as random variables, allowing Bayes rule $p(y|x) = p(x|y)p(y)/p(x)$ to be used to perform inference. This approach is named after the Reverend Thomas Bayes.

Bias – An estimator is biased if its expectation differs from the true value; the bias of the estimator is the difference between its expectation and the truth.

Consistency – A sequence of estimators is consistent if it converges, as the number of samples approaches infinity, to the true value. Such a sequence is asymptotically unbiased.

Expectation – The expectation (or expected value) of a random variable is, in a sense, the mean value that an infinite ensemble of independent replicates would have. In some sense, it quantifies the value which one would expect a realization to have, but there is no requirement that the expectation is a value which the random variable can take: for example, a Bernoulli random variable with parameter p can take values 0 and 1, but has expectation p .

iid (independent and identically distributed) – A collection of random variables is said to be iid if those variables are independent and share a common distribution. That is, each may be considered to be a single realization of the same probability distribution.

Independent – Random variables are independent if knowledge of one provides no information about the others. Formally, one can require that the conditional distribution of any one of the random variables given the other is the marginal distribution of that random variable, that is, $p_{Y|X}(y|x) = p_Y(y)$ if X and Y are independent.

Markov chain – A temporally ordered collection of random variables with the property that conditional upon the present, the future is independent of the past.

mathematical problems, which make fundamental use of random samples. Markov chain Monte Carlo (MCMC) uses a particular type of (usually discrete time) Markov process to obtain collections of dependent variables. Integration and optimization can both be addressed within this framework; this article concentrates on the former although it also touches on the latter.

The Monte Carlo method as it is understood today was born in Los Alamos in the 1940s, when physicists working on particle transport problems began solving them using something which they termed the Monte Carlo method. (Although earlier examples of Monte Carlo techniques exist, the cost of carrying out the experiments rendered them largely impractical and of only specialist interest.) The precise origin of the name varies from one account to another, but there is general agreement that it stems from its relationship with the games of chance played in the casinos of Monte Carlo. The first revolutionary step introduced at this time was the use of (pseudo)random number generators in place of physical experiments to perform the calculation. The second was the realization that it is not necessary to use collections of independent random variables of known distribution: this is the concept which leads to MCMC. The physics community has continued to contribute to the development of Monte Carlo methodology, especially MCMC, to the present day.

During the 1980s, the increasing use of Bayesian methods and the associated need to evaluate complex, high-dimensional integrals led to a renewed interest in and development of MCMC methods by the statistics community. This was the point at which the use of Monte Carlo methods to approximate general integral expressions, particularly expectations with respect to complicated probability distributions, became widespread. The increased interest also drove – and continues to drive – the development of methodology and theory amongst researchers outside of the traditional application domains of Monte Carlo integration.

In Bayesian statistics, it is extremely common for inferential techniques to require the calculation of expectations with respect to probability distributions which are known only up to a normalising constant and, furthermore, from which it is not possible to obtain samples. Although simple Monte Carlo techniques such as rejection and importance sampling are formally very general, they both require a good proposal distribution in order to work efficiently. These can be difficult to design, particularly in high-dimensional

Background and History

Monte Carlo methods may be thought of as computational techniques for the (usually approximate) solution of

problems. MCMC is a technique which has been developed to provide a method for calculating expectations under high-dimensional (and generally difficult to sample from) distributions.

Markov Chains and MCMC

Markov Chains

A discrete-time Markov chain is, roughly speaking, some collection of random variables with a temporal ordering which have the property that conditional upon the present, the future does not depend upon the past. This concept, which can be viewed as a form of something known as the Markov property, can be formalized by saying that a collection of random variables X_1, X_2, \dots forms a Markov chain if, and only if, the joint pdf of the first n elements of the sequence may be decomposed in the following manner for any value of n :

$$p(x_1, \dots, x_n) = p(x_1)p(x_2|x_1) \dots p(x_n|x_{n-1})$$

Although a class of continuous-time stochastic processes with a similar lack-of-memory property can be defined, these are rarely used in an MCMC context.

The basic idea behind MCMC is that, if it is possible to construct a Markov chain such that a sequence of draws from that chain has similar statistical properties (in some sense) to a collection of draws from a distribution of interest, then it is also possible to estimate expectations with respect to that distribution by using the standard Monte Carlo estimator but using the dependent collection of random variables obtained by simulating a Markov chain rather than an independent collection.

A few concepts are required to understand how a suitable chain can be constructed. The conditional probability densities $p(x_n|x_{n-1})$ are often termed transition kernels, as they can be thought of as the probability density associated with a movement from x_{n-1} to x_n . If $p(x_n|x_{n-1})$ does not depend directly upon the value of n , then the associated Markov chain is termed time homogeneous (as its transitions have the same distribution at all times). A time homogeneous Markov chain with transition kernel k , is said to have a probability density f as an invariant or stationary distribution if

$$\int f(x)k(y|x)dx = f(y)$$

If a Markov chain satisfies a condition known as detailed balance with respect to a distribution, then it is reversible (in the sense that the statistics of the time-reversed process match those of the original process) and hence invariant with respect to that distribution. The detailed balance condition states, simply, that the probability of starting at x and moving to y is equal to the probability of starting at y

and moving to x . Formally, given a distribution f and a kernel k , one requires that $f(x)k(y|x) = f(y)k(x|y)$ and simple integration of both sides with respect to x proves invariance with respect to f under this condition.

The principle of most MCMC algorithms is that, if a Markov chain has an invariant distribution, f , and (in some suitable sense) forgets where it has been, then using its sample path to approximate integrals with respect to f is a reasonable thing to do. This can be formalized under technical conditions to provide an analog of the law of large numbers (often termed the ergodic theorem) and the central limit theorem. The first of these results tells us that we can expect the sample average to converge to the appropriate expectation with probability one as the number of samples becomes large enough; the second tells us that the estimator we obtain is asymptotically normal with a particular variance (which depends upon the covariance of the samples obtained, demonstrating that it is important that the Markov chain forgets where it has been reasonably fast). These conditions are not always easy to verify in practice, but they are important: it is easy to construct examples which violate these conditions and have entirely incorrect behavior.

In order to use this strategy to estimate expectations of interest, it is necessary to construct Markov chains with the correct invariant distribution. There are two common approaches to this problem.

Gibbs Sampling

The first approach is termed Gibbs sampling, and relies on the ability to sample from the conditional distributions of the target distribution. It can be motivated heuristically by the idea that, given a joint distribution one might hope that sampling iteratively from its conditional distributions would ultimately provide a sample from the joint distribution. This can be analyzed by considering the Markov chain that results from the procedure and it can be shown that under suitable conditions this is the case.

More formally, if the target distribution is p over some space which can be factorized into d elements (such as $\mathbb{R}^d = \mathbb{R} \times \dots \times \mathbb{R}$), it is possible to write realizations of the associated random variable as $x^{1:d} = (x^1, \dots, x^d)$ and define $x^{-j} = (x^1, \dots, x^{j-1}, x^{j+1}, \dots, x^d)$ as the random variable excluding its j th component. Gibbs sampling then proposes the use of a collection of d kernels, with $k_j(x_j|x_{-j}) = \delta(x_{j-1}^{-j} - x_{j-1}^{-j})p(x_j^j|x_{-j}^{-j})$ (where δ denotes the Dirac delta measure which places probability one on its argument taking the value zero). That is, the j th kernel keeps all but the j th elements unchanged and samples that component from its conditional distribution given the remaining components. These d kernels can be applied in a deterministic order (systematic scan Gibbs-sampling) or stochastically (random-scan Gibbs sampling).

To verify that Gibbs sampling leads to the correct invariant distribution it suffices for each of the kernels to have the correct invariant distribution independently, and this is trivially so, because

$$\begin{aligned} & \int p(x_{t-1})k_j(x_t|x_{t-1})dx_{t-1} \\ &= \int p(x_{t-1})p(x_t^j|x_{t-1}^{-j})\delta(x_{t-1}^{-j} - x_t^{-j})dx_{t-1} \\ &= p(x_t^{-j})p(x_t^j|x_t^{-j}) = p(x_t) \end{aligned}$$

Gibbs sampling provides a simple algorithm with the properties which are required, but it does require that a suitable collection of conditional distributions are known and can be sampled from and it can perform poorly if the distribution has strongly correlated components (although this can sometimes be addressed by reparameterization). The difficulty with sampling from suitable conditional distributions is a real one for many interesting problems. Even if a closed-form expression for these distributions can be obtained (and this is not often the case), it is often impossible to obtain samples from them.

Figures 1(a) and **1(b)** illustrate the difficulty with correlated random variables. The first shows the trajectory of a Gibbs sampler targeting an uncorrelated bivariate normal distribution; the second shows the trajectory for a highly correlated case. When the variables are highly correlated, conditional upon the knowledge of one the distribution of the other is concentrated and the typical moves are very small leading to a poor exploration of the distribution on a global scale. In **Figure 1(b)** it can be seen that this results in the sampler failing to explore the majority of the distribution. In the Gaussian case, one

could solve this by reprojecting the problem onto the space of eigenvectors of the covariance matrix, and hence eliminating the correlation (in fact, in the Gaussian case this renders the two variables independent), but such reparametrizations can be difficult to find in general.

A technique closely related to Gibbs sampling is based upon the same principle as rejection sampling: obtaining samples of a random variable with density f is equivalent to obtaining samples uniformly from the region beneath the density and discarding the additional dimension. Slice sampling, rather than using rejection sampling to produce samples uniformly from such a region, constructs a Markov chain which has as the uniform distribution over such a region as its stationary distribution. There are a number of difficulties associated with implementing slice samplers in practice.

The Metropolis–Hastings Algorithm

A more general strategy is clearly needed for many interesting problems. The Metropolis–Hastings algorithm is one of a number of algorithms which were proposed to impose detailed balance on a Markov chain using a rejection mechanism: a general proposal kernel is used, but with some probability the chain remains in its present position rather than accepting the new value. It has been shown to be optimal among those algorithms in the sense that it has a smaller associated variance than other options. Intuitively, the algorithm proceeds at each iteration by sampling a proposed value, and this value is accepted with a probability which corrects for the relative probability of the state under the proposal and target distributions.

Figure 1 Gibbs sampling: (a) the uncorrelated case and (b) the correlated one. The solid line shows the trajectory of the first hundred samples; dashed lines are contours of the distribution.

If rejection occurs the existing state is replicated — notice this difference from the simple rejection sampling algorithm. More formally, the algorithm for sampling from p using a proposal q proceeds at iteration t as

1. Sample $X' \sim q(\cdot | X_{t-1})$.
2. Calculate

$$\alpha(X_{t-1}, X') = \frac{p(X')q(X_{t-1}|X')}{p(X_{t-1})q(X'|X_{t-1})}.$$

3. Sample $U \sim \mathcal{U}[0, 1]$.
4. If $U \leq \alpha$, set $X_t = X'$.
5. Otherwise, set $X_t = X_{t-1}$.

The acceptance probability α depends upon only the ratio of the target probability density at the proposed point to that at the current point (in addition to the ratio of proposal densities). This has the significant consequence that it is only necessary to evaluate the density up to a normalizing constant. One common choice of q is a symmetric random-walk kernel (such as a Gaussian distribution centered on the previous value). In this case, the acceptance probability α simplifies to $p(X')/p(X_{t-1})$ due to the symmetry of the proposal kernel. This approach is often referred to as the random-walk Metropolis algorithm and corresponds to the first MCMC algorithm to be proposed. Another choice, leading to something termed the independence sampler, is to employ a proposal distribution which is entirely independent of the previous position. Of course, situations between these two extremes exist and often produce better results (e.g., using a proposal comprising a mixture of a diffuse proposal distribution and a local random walk). It is also noteworthy that Gibbs sampling may be interpreted as a Metropolis–Hastings algorithm in which a particular choice of proposal kernel is made, guaranteeing that $\alpha = 1$ at all times (i.e., every proposed value is accepted). Although the Metropolis–Hastings algorithm allows a broad range of models to be explored, care is still required to design algorithms with proposals which allow a thorough exploration of the space and to assess their convergence. In order for a sampler to perform well, it is necessary for it to explore the entire support of the distribution and to move around it quickly. This can only be achieved through the use of good proposal distributions.

By way of an example, consider the random-walk Metropolis–Hastings algorithm. In contrast to the rejection sampling case, it is not desirable to maximize the acceptance probability of proposed moves in such an algorithm. Using a very small proposal variance leads to moves which are almost always accepted (α is always close to one if the density is continuous and proposed moves are small) but movements are all very small, leading to poor

exploration of the distribution on a global scale. In contrast, if a very large proposal variance is used then most moves are proposed in regions of very little probability and many moves are rejected, leading to the sampler sticking with a single value for many iterations. Somewhere in between, good performance can often be obtained. In addition to illustrating these phenomena for a simple example, **Figure 2** illustrates a simple qualitative approach to checking for convergence: looking at traces of the Markov chain – do they move well and do they cover the entire space? Notice that the high variance proposal produces a reasonable looking histogram because of a poor choice of bin width and the low variance proposal would appear to explore the space well if it was not known that there were three modes. A common feature of such diagnostic approaches is that great care is required in order to reach the correct conclusions.

Simulated Annealing

Another common MCMC algorithm, albeit one which is often considered in isolation, is simulated annealing (SA). This is an optimization, rather than integration, algorithm which simulates a time inhomogeneous Markov chain which is intended to provide samples from the regions of parameter space which minimize some objective function. Given a function, $H(x)$, which one wishes to find the minima of (usually the function of interest, but it can be any other function which shares its minimizers), SA provides a numerical method for locating its minima.

Modeled upon the physical annealing processes, SA employs densities proportional to $\exp(-\beta H(x))$ in order to find the value(s), x^* , of its argument which minimize $H(x)$. Corresponding to an inverse temperature in physical annealing, β controls how concentrated these distributions are about the optima: if $\beta \ll 1/H(x^*)$ then the distribution is very flat; as $\beta \rightarrow \infty$ the distribution becomes singular with all of its mass located at the optima.

The simulated annealing algorithm simulates a Markov chain with one such distribution as its invariant distribution at each iteration using the same mechanism as the Metropolis–Hastings algorithm. However, β is gradually increased as the algorithm runs leading to a time-inhomogeneous chain. This allows a single simulation run to be initiated at small β , allowing the chain to explore the space well, and to reach the minimizers which have increasing mass as β increases. Selecting the sequence of values taken by β is nontrivial; if it increases too quickly the simulation will become trapped in a local optimum but the more slowly it increases the more expensive each simulation becomes.

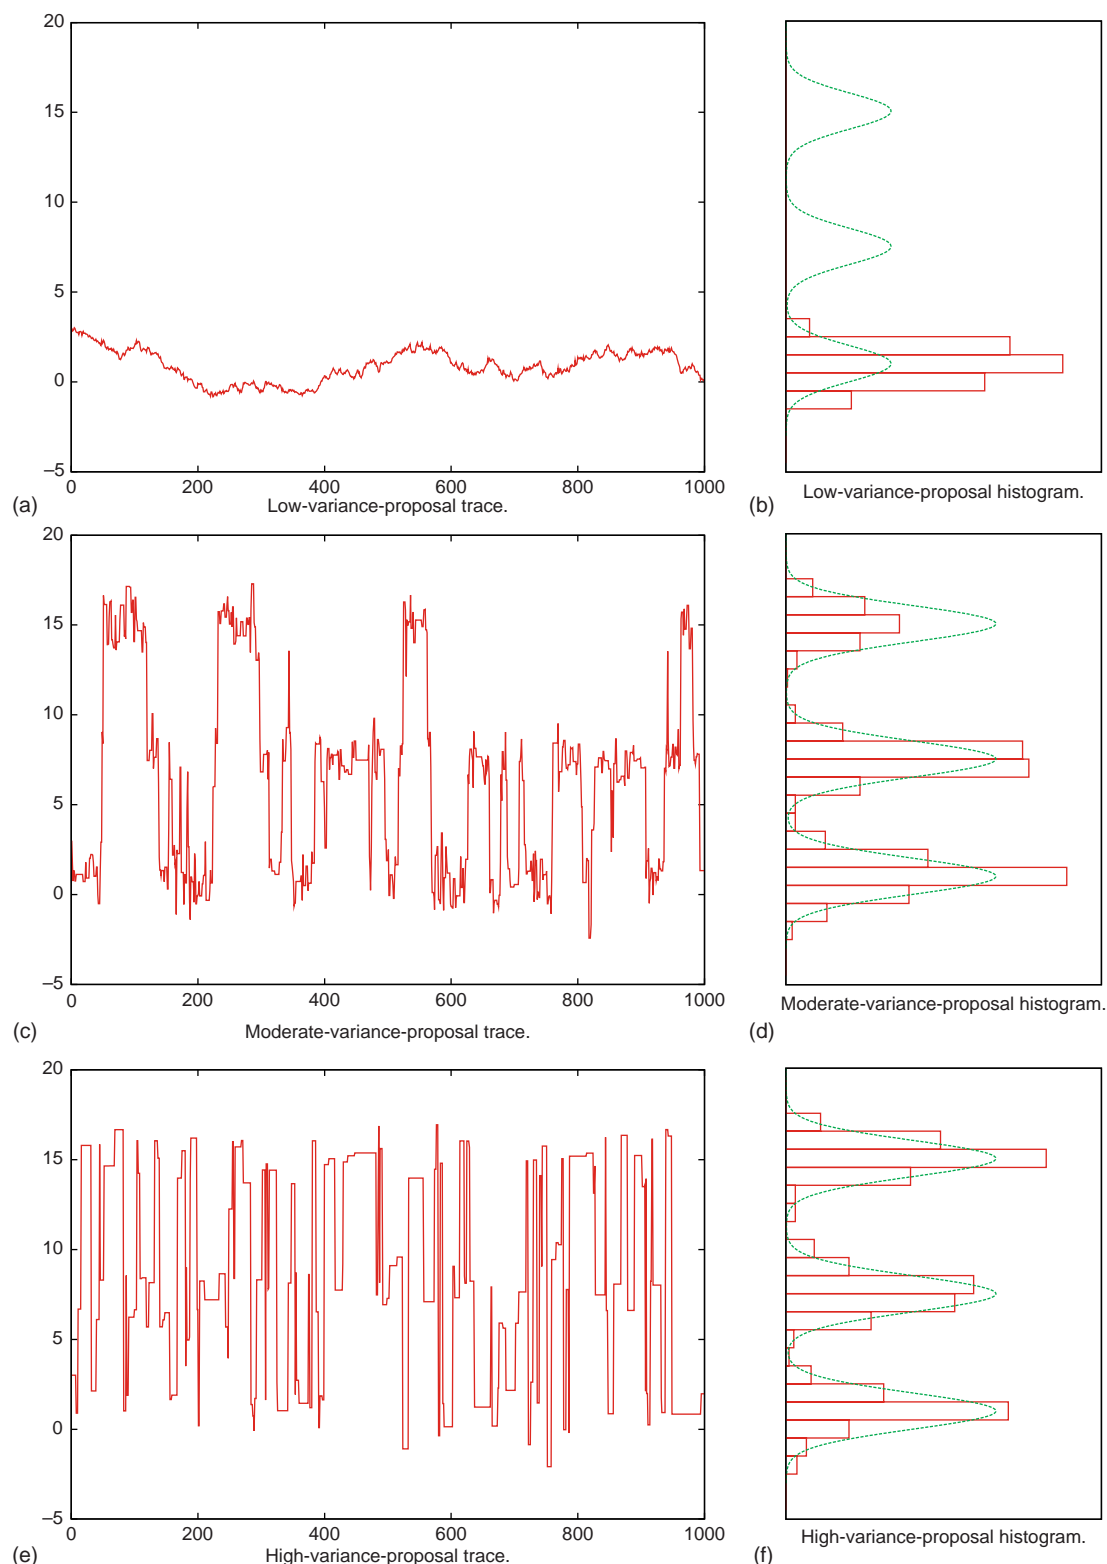

Figure 2 Random-walk Metropolis output: sample sequences and associated histograms (with target density illustrated) for three variances of proposal kernel – (a) low-variance-proposal trace; (b) low-variance-proposal histogram; (c) moderate-variance-proposal trace; (d) moderate-variance-proposal histogram; (e) high-variance-proposal trace; and (f) high-variance-proposal histogram.

Implementation of MCMC Algorithms

Sample Quality

As an MCMC algorithm is rarely initialized from its invariant distribution, there might be some concern that its initial values might bias results even if it does approach this equilibrium distribution later on. To compensate for this, a burn-in period is often implemented: the first N samples being discarded, with N being chosen to be large enough that the chain has reached its stationary regime by this time.

In order to reduce the correlation between samples provided by an MCMC algorithm, it was once popular to thin the chain by recording only every k th value produced by the sampler. In fact, this increases the variance and is undesirable. However, if only limited memory is available then it is possible to improve performance by running a longer chain and keeping every k th value rather than running a shorter chain.

Assessing Convergence

It is also important to assess whether the Markov chain has converged to its stationary distribution. That is, does the chain explore the space fast enough, relative to the number of samples that have been obtained, that the samples produced by it provide a good representation of the stationary distribution of the chain? In general, this is a difficult task. As illustrated in **Figure 2** graphs of sample values against iteration number can provide some information, but are far from infallible. Looking at parameter traces of this form is one common qualitative technique for the assessment of convergence. Unfortunately, it suffers from the problem that it only provides a characterization of the behavior of the chain in the region that it *has* explored. This means that such a technique will fail to diagnose at least one problem: a failure of the chain to reach all parts of the space.

Numerous quantitative methods have been developed. Some of these make use of the output of single chain; these suffer from a similar problem to the simple graphical method. Other employ an ensemble of simulation runs, comparing the output produced by several chains by various techniques – in this case, the usefulness of the resulting analysis can be sensitive to the initialization of these chains. An enormous literature has developed around the assessment of convergence of MCMC methods and it is not possible to adequately summarize that literature here.

Using the Sample

The most direct use that can be made of the sample obtained from an MCMC algorithm is to estimate the sample average of some quantity of interest, and to use this as a proxy for the expectation of that quantity under

the stationary distribution of the Markov chain. However, the sample actually provides an approximate representation of the entire distribution of the quantity of interest and one can use this to obtain considerably more information. For example, given a one-dimensional function, φ , from the space in which samples were obtained to a real number, its full distribution can be summarized using a histogram of its values at the sample points. Summary statistics, such as quantiles, can be obtained in the same manner. For example, if one orders the samples obtained such that $\varphi(x_1) < \varphi(x_2) < \dots < \varphi(x_n)$ then the q th percentile of the distribution of $\varphi(X)$ under the stationary distribution of the Markov chain may be approximated with $\varphi(x_{nq/100})$.

Model Selection

In many settings, often those involving model selection it is useful to have an algorithm which can deal with a collection of densities defined over spaces of different dimension (e.g., consider choosing not just the parameters of a mixture model, but also the number of mixture components). Doing this is technically nontrivial, as the densities are not comparable (just as the mass per unit area of a sheet of steel cannot be compared directly with the density of a steel block). One solution to this problem is termed Reversible Jump Markov chain Monte Carlo and, loosely speaking, it employs a dimension-matching construction in order to produce a Markov chain which explores these spaces of differing dimension whilst retaining reversibility.

Software

Implementing Monte Carlo methods in standard statistical environments is possible, but can be challenging. A number of specialized software packages have been developed to allow nonspecialists to efficiently employ these techniques. Among these are WinBUGS (Bayesian inference Using Gibbs Sampling) a rather general environment for performing MCMC which allows for many algorithms other than Gibbs sampling to be employed and MLWin, a package designed specifically for Bayesian multilevel modeling. Although still not entirely automatic, these programs dramatically simplify the use of these algorithms and provide some amount of support in the assessment of convergence and related issues. However, care is still used to ensure that meaningful results are obtained.

Selected Recent Developments

Although MCMC has driven a revolution in statistics over the past decades, it has limitations. Assessment of convergence is difficult, considerable effort is required to produce efficient samplers and some problems remain

intractable. In order to address these difficulties, particularly the final two, a number of extensions and novel techniques have been developed in recent years.

Perfect simulation is a technique which has been developed to combat the difficulties associated with convergence assessment and the use of a collection of variables which are not iid. Under particular (and, unfortunately, somewhat restrictive) circumstances it is possible to obtain a single sample with the correct distribution by simulating a Markov Chain in such a way that its final value is independent of its beginnings. In order to prevent bias associated with the time at which the sample is produced, considerable care is required in the design of such algorithms.

Two approaches have been developed to reduce the amount of work required to design an efficient sampler. One is to adaptively tune the parameters of the proposal distribution as a sampler is run (ensuring that these lead to the correct distribution introduces nontrivial technical difficulties and this should not be done without thorough consideration of these issues). The other involves using the entire history of the Markov chain as a representation of the distribution of interest and incorporating this into the proposal distribution (again, this is nontrivial to implement in a theoretically justifiable manner).

Finally, much research has been done recently in the area of population-based methods (going under various names: annealed importance sampling, population Monte Carlo, and sequential Monte Carlo – the last of these proposed frameworks encompasses almost all proposed techniques to date). These approaches use a collection of many samples at each iteration and propagate this population around using importance sampling techniques, combined with elements of MCMC. These techniques show great promise and real applications have been developed in the past few years.

Applications

This section provides sketches of two recent areas of educational statistics which have benefited from the use of MCMC methods; these examples show the general usefulness of the techniques but it should be understood that the methods described previously can be used to perform inference in almost any complex statistical model.

Item Response Theory

There has been much recent work on Bayesian inference in item response theory (IRT), employing MCMC algorithms to characterize the posterior distribution of interest. This area is of great importance to test theory, but has been hampered until recently by difficulties associated with performing inference for realistic models.

In a typical IRT model, one has J discrete observations for each of I individuals. Typically, each observation describes performance on a single examination or some other assessment. These results are modeled as a noisy observation of an underlying, unobserved, proficiency influenced by a collection of other factors (some of which vary upon an individual basis; others by assessment criterion). This rapidly leads to a complex model, particularly when factors such as missing observations and variation in the types of assessment are taken into account. Recently developed MCMC algorithms which combine Metropolis–Hastings and Gibbs sampler elements have provided tools which allow the use of models of realistic complexity.

Sensitivity Analysis in Hierarchical Models

Sensitivity analysis is an assessment of the sensitivity of a mathematical model to its modeling assumptions. In statistics, it is often used to determine how sensitive inferences made using a particular model are to the parameters of that model. This is of great importance in real inferential settings, but can be difficult when dealing with complex models.

In addition to inferential tasks, it is possible to use MCMC output to perform sensitivity analysis. A recent application in the field of educational statistics (Seltzer *et al.*, 2002), for example, considered two-level hierarchical models in which the first level corresponded to individual effects and the second to site effects. Particular examples included the efficacy of remedial reading intervention. Using MCMC rather than traditional techniques made it straightforward to employ non-normal distributions in order to ameliorate the effect of outlying observations.

Definition, Basic Operations, and Fundamental Properties of Matrix Algebra

Definition and Terminology

A rectangular array of numbers is called a matrix. A matrix with n rows and p columns is referred as an $n \times p$ matrix. If a matrix has n rows and 1 column, it is called an n -dimensional column vector. If a matrix has 1 row and p columns, it is called a p -dimensional row vector. A matrix with 1 row and 1 column, that is, a single numerical value, is called a scalar. A matrix divided into submatrices is called a partitioned matrix.

Boldface capital letters (e.g., \mathbf{A}) are used to represent a matrix. The element in row i and column j of a matrix \mathbf{A} is represented as a_{ij} . Boldface lower letters (e.g., \mathbf{a}) are used to represent a vector.

Some basic types of matrices are listed in Table 1.

Basic Operations

Several matrix operations such as matrix addition and matrix multiplication are given in Table 2.

It should be noted that matrix multiplication is not exchangeable, that is, $\mathbf{AB} \neq \mathbf{BA}$ in general. If $\mathbf{AB} = \mathbf{BA}$, then \mathbf{A} and \mathbf{B} are said to be commutative. If \mathbf{A} is not a null matrix and $\mathbf{A}^2 = \mathbf{O}$, \mathbf{A} is said to be nilpotent. If \mathbf{A} is a square matrix and $\mathbf{A}^2 = \mathbf{A}$, then \mathbf{A} is said to be idempotent.

If \mathbf{A} and \mathbf{B} are partitioned as

$$\mathbf{A} = \begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} \mathbf{B}_{11} & \mathbf{B}_{12} \\ \mathbf{B}_{21} & \mathbf{B}_{22} \end{bmatrix}$$

and all $\mathbf{A}_{ij} + \mathbf{B}_{ij}$ are defined, then the sum of $\mathbf{A} + \mathbf{B}$ is written as

$$\mathbf{A} + \mathbf{B} = \begin{bmatrix} \mathbf{A}_{11} + \mathbf{B}_{11} & \mathbf{A}_{12} + \mathbf{B}_{12} \\ \mathbf{A}_{21} + \mathbf{B}_{21} & \mathbf{A}_{22} + \mathbf{B}_{22} \end{bmatrix}$$

If all $\mathbf{A}_{ik} \mathbf{B}_{kj}$ ($i, j, k = 1, 2$) are present, then the product of \mathbf{AB} is written as

$$\mathbf{AB} = \begin{bmatrix} \mathbf{A}_{11}\mathbf{B}_{11} + \mathbf{A}_{12}\mathbf{B}_{21} & \mathbf{A}_{11}\mathbf{B}_{12} + \mathbf{A}_{12}\mathbf{B}_{22} \\ \mathbf{A}_{21}\mathbf{B}_{11} + \mathbf{A}_{22}\mathbf{B}_{21} & \mathbf{A}_{21}\mathbf{B}_{12} + \mathbf{A}_{22}\mathbf{B}_{22} \end{bmatrix}$$

Following are some properties of the transpose. (1) $(\mathbf{A}')' = \mathbf{A}$. (2) $(\mathbf{AB})' = \mathbf{B}' \mathbf{A}'$. (3) $(\mathbf{A} + \mathbf{B})' = \mathbf{A}' + \mathbf{B}'$. (4) $\mathbf{A}' = \mathbf{A}$ if \mathbf{A} is symmetric. Furthermore,

$$(5) \begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{bmatrix}' = \begin{bmatrix} \mathbf{A}_{11}' & \mathbf{A}_{21}' \\ \mathbf{A}_{12}' & \mathbf{A}_{22}' \end{bmatrix}$$

Following are some properties of the trace. (1) $\text{tr}(\mathbf{A}) = \text{tr}(\mathbf{A}')$. (2) $\text{tr}(\mathbf{A} + \mathbf{B}) = \text{tr}(\mathbf{A}) + \text{tr}(\mathbf{B})$. (3) $\text{tr}(k\mathbf{A}) = k \text{tr}(\mathbf{A})$. (4) $\text{tr}(\mathbf{CD}') = \text{tr}(\mathbf{D}'\mathbf{C})$.

For two n -dimensional vectors $\mathbf{a} = (a_1, a_2, \dots, a_n)'$ and $\mathbf{b} = (b_1, b_2, \dots, b_n)'$, their inner product is the sum of products of corresponding components and denoted as

$$\mathbf{a} \cdot \mathbf{b} = \mathbf{a}'\mathbf{b} = \sum a_i b_i$$

For n -dimensional vector \mathbf{a} , its length or norm is defined by the square root of the sum of its squared components,

$$\|\mathbf{a}\| = (\mathbf{a}'\mathbf{a})^{1/2} = \left(\sum a_i^2 \right)^{1/2}$$

The inner product of two vectors \mathbf{a} and \mathbf{b} equals zero if they are orthogonal. Let θ be the angle between two non-null vectors \mathbf{a} and \mathbf{b} of the same order. Using inner product and norm of vectors, we obtain

$$\cos \theta = \frac{\mathbf{a} \cdot \mathbf{b}}{\|\mathbf{a}\| \|\mathbf{b}\|}$$

If $\mathbf{a} \cdot \mathbf{b} = 0$, then $\cos \theta = 0$.

Rank

Vectors $\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_p$ are called linearly dependent if scalars k_1, k_2, \dots, k_p exist, not all zero, such that $k_1\mathbf{a}_1 + k_2\mathbf{a}_2 + \dots + k_p\mathbf{a}_p = \mathbf{0}$. If no such scalars exist then the p vectors are called linearly independent.

The rank of a matrix \mathbf{A} is defined as the maximum number of linearly independent column or row vectors in \mathbf{A} . The maximum rank of an $n \times p$ matrix \mathbf{A} is $\min(n, p)$. It is defined to have full row rank if $\text{rank}(\mathbf{A}) = n (\leq p)$, and is defined to have full column rank if $\text{rank}(\mathbf{A}) = p (\leq n)$. If a matrix has both row full rank and column full rank, it is called nonsingular. Obviously, a nonsingular matrix is square. An $n \times n$ matrix of rank less than n is called singular.

Following are some properties of rank. (1) $0 \leq \text{rank}(\mathbf{A}) \leq \min(n, p)$, \mathbf{A} is an $n \times p$ matrix. (ii) $\text{rank}(\mathbf{A}) = \text{rank}(\mathbf{A}')$. (iii) $\text{rank}(\mathbf{A}) = \text{rank}(\mathbf{AA}') = \text{rank}(\mathbf{A}'\mathbf{A})$. (iv) If \mathbf{A} and \mathbf{B} are $n \times p$ matrices and $(\mathbf{A} : \mathbf{B})$ is an $n \times 2p$ matrix consisting of elements of the matrix \mathbf{B} written to the right of the elements of \mathbf{A} , $\text{rank}(\mathbf{A} + \mathbf{B}) \leq \text{rank}(\mathbf{A} : \mathbf{B}) \leq \text{rank}(\mathbf{A}) + \text{rank}(\mathbf{B})$, and (v) $\text{rank}(\mathbf{A}) + \text{rank}(\mathbf{B}) - \text{rank}(\mathbf{A} : \mathbf{B}) \leq \text{rank}(\mathbf{AB}') \leq \min(\text{rank}(\mathbf{A}), \text{rank}(\mathbf{B}))$. (vi) $\text{rank}(\mathbf{BAC}) = \text{rank}(\mathbf{A})$, if \mathbf{B} and \mathbf{C} are nonsingular matrices.

Table 1 Examples of basic type of matrices

Name	Definition	Example
Rectangular	$n \times p$	$\begin{bmatrix} 1 & 2 & 3 \\ -4 & 5 & 6 \end{bmatrix}$
Column vector	$n \times 1$	$\begin{bmatrix} 1 \\ 4 \end{bmatrix}$
Row vector	$1 \times p$	$[1 \ 2 \ 3]$
Scalar	1×1	$[1]$
Square	$n \times n$	$\begin{bmatrix} 1 & 2 \\ 4 & 5 \end{bmatrix}$
Symmetric	Square $a_{ij} = a_{ji}$	$\begin{bmatrix} 1 & 2 \\ 2 & 5 \end{bmatrix}$
Diagonal	Square $a_{ij} = 0$ for $i \neq j$	$\begin{bmatrix} 1 & 0 \\ 0 & 5 \end{bmatrix}$
Identity (I)	Square $a_{ii} = 1$ $a_{ij} = 0$ for $i \neq j$	$\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$
Upper/lower triangular	Square $a_{ij} = 0$ below/above the diagonal	$\begin{bmatrix} 1 & 2 & 3 \\ 0 & 5 & 6 \\ 0 & 0 & 9 \end{bmatrix}$
Unit vector (1)	$a_i = 1$	$\begin{bmatrix} 1 \\ 1 \end{bmatrix}$
Unit matrix (J)	$a_{ij} = 1$	$\begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix}$
Null(zero) matrix (0)	$a_{ij} = 0$	$\begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}$

Vector Spaces

The set of all n -dimensional vectors is called the n -dimensional Euclidian space and is denoted as E^n . Then a subset S of E^n is said to be the vector subspace (or vector space for short) if any linear combinations of vectors in S are also in the set. The maximum number of linearly independent vectors in a vector space is referred to as the dimension of the vector space. Since rank of a matrix is defined as the maximum number of linearly independent column or row vectors in the matrix, a matrix **X** spans a vector space $S(\mathbf{X})$ whose dimension is equal to $\text{rank}(\mathbf{X})$.

A maximal linearly independent set of vectors in a vector space composes a basis of the vector space. A basis of a vector space is called an orthonormal basis if the vectors in the basis are orthogonal to each other and of unit norms.

In addition, the set of all vectors orthogonal to all the vectors in $S(\mathbf{X})$ is called the orthogonal complement subspace of $S(\mathbf{X})$ in E^n and denoted as $S(\mathbf{X})^\perp$.

Determinants

If **A** is a 2×2 square matrix, the determinant of **A** is calculated as

$$|\mathbf{A}| = \begin{vmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{vmatrix} = a_{11}a_{22} - a_{12}a_{21}$$

If **A** is a 3×3 square matrix, the determinant of **A** is calculated as

$$|\mathbf{A}| = \begin{vmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{vmatrix} = \begin{vmatrix} a_{11}a_{22}a_{33} & -a_{12}a_{21}a_{33} \\ -a_{13}a_{22}a_{31} & -a_{11}a_{23}a_{32} \\ +a_{12}a_{23}a_{31} & +a_{13}a_{21}a_{32} \end{vmatrix}$$

The general definition of the determinant of an $n \times n$ square matrix **A** is

$$|\mathbf{A}| = \sum (-1)^{t(j)} a_{1j_1} a_{2j_2} \dots a_{nj_n}$$

where $t(j)$ is the number of transpositions in a permutation of j_1, j_2, \dots, j_n and the summation is taken over all permutations. $|\mathbf{A}| \neq 0$ if **A** is nonsingular. $|\mathbf{A}| = 0$ if **A** is singular. If **A** is triangular or diagonal, $|\mathbf{A}| = \prod a_{ii}$.

Following are some properties of determinants. (1) $|k\mathbf{A}| = k^n |\mathbf{A}|$. (2) $|\mathbf{A}'| = |\mathbf{A}|$. (3) $|\mathbf{A}^{-1}| = |\mathbf{A}|^{-1}$. (4) $|\mathbf{AB}| = |\mathbf{A}||\mathbf{B}| = |\mathbf{B}||\mathbf{A}| = |\mathbf{BA}|$, matrices of the same order. (5) $|\mathbf{A} + \mathbf{BC}| = |\mathbf{A}| |\mathbf{I}_n + \mathbf{A}^{-1}\mathbf{BC}| = |\mathbf{A}| |\mathbf{I}_p + \mathbf{CA}^{-1}\mathbf{B}|$, **B** and **C'** are $n \times p$ matrices. Furthermore,

$$(6) \begin{vmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{vmatrix} = |\mathbf{A}||\mathbf{D} - \mathbf{CA}^{-1}\mathbf{B}| = |\mathbf{D}||\mathbf{A} - \mathbf{BD}^{-1}\mathbf{C}|$$

if **A** and **D** are nonsingular matrices.

Inverse Matrix

The inverse of a square matrix **A** is the unique matrix \mathbf{A}^{-1} which satisfies $\mathbf{AA}^{-1} = \mathbf{A}^{-1}\mathbf{A} = \mathbf{I}$. The inverse exists if and only if **A** is nonsingular, that is, $|\mathbf{A}| \neq 0$.

If **A** is a 2×2 matrix,

$$\mathbf{A}^{-1} = \frac{1}{a_{11}a_{22} - a_{12}a_{21}} \begin{bmatrix} a_{22} & -a_{12} \\ -a_{21} & a_{11} \end{bmatrix}$$

Following are some properties of inverse matrix. (1) $(k\mathbf{A})^{-1} = (1/k)\mathbf{A}^{-1}$. (2) $(\mathbf{A}^{-1})^{-1} = \mathbf{A}$. (3) $(\mathbf{A}')^{-1} = (\mathbf{A}^{-1})'$. (4) $(\mathbf{AB})^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1}$. Furthermore, if **A** is an $n \times n$ nonsingular matrix; **B** as an $n \times p$ matrix; **C** as a $p \times n$ matrix; and **D** as a $p \times p$ nonsingular matrix,

$$(5) (\mathbf{A} + \mathbf{BDC})^{-1} = \mathbf{A}^{-1} - \mathbf{A}^{-1}\mathbf{B}(\mathbf{D}^{-1} + \mathbf{CA}^{-1}\mathbf{B})^{-1}\mathbf{CA}^{-1}$$

$$(6) \begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{bmatrix}^{-1} = \begin{bmatrix} \mathbf{A}^{-1} + \mathbf{A}^{-1}\mathbf{BECA}^{-1} & -\mathbf{A}^{-1}\mathbf{BE} \\ -\mathbf{ECA}^{-1} & \mathbf{E} \end{bmatrix} = \begin{bmatrix} \mathbf{F} & -\mathbf{FBD}^{-1} \\ -\mathbf{D}^{-1}\mathbf{CF} & \mathbf{D}^{-1} + \mathbf{D}^{-1}\mathbf{CFBD}^{-1} \end{bmatrix}$$

where $\mathbf{E} = (\mathbf{D} - \mathbf{CA}^{-1}\mathbf{B})^{-1}$ and $\mathbf{F} = (\mathbf{A} - \mathbf{BD}^{-1}\mathbf{C})^{-1}$

Table 2 Selected basic matrix operations

Operation	Example
Addition/subtraction $\mathbf{A} \pm \mathbf{B} = [a_{ij} \pm b_{ij}]$ \mathbf{A}, \mathbf{B} of the same order	$\begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{bmatrix} + \begin{bmatrix} 1 & 2 & 0 \\ 4 & 1 & -2 \end{bmatrix} = \begin{bmatrix} 2 & 4 & 3 \\ 8 & 6 & 4 \end{bmatrix}$
Scalar multiplication $k\mathbf{A} = [k a_{ij}]$	$2 \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{bmatrix} = \begin{bmatrix} 2 & 4 & 6 \\ 8 & 10 & 12 \end{bmatrix}$
Matrix multiplication $\mathbf{AB} = [\sum_k a_{ik} b_{kj}]$ $\mathbf{A}_{n \times p}, \mathbf{B}_{p \times m}$	$\begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{bmatrix} \begin{bmatrix} 1 & -4 \\ 2 & 1 \\ 0 & -2 \end{bmatrix} = \begin{bmatrix} 5 & -8 \\ 14 & -23 \end{bmatrix}$
Transpose $\mathbf{A}' = [a_{ji}]$	$\begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{bmatrix}' = \begin{bmatrix} 1 & 4 \\ 2 & 5 \\ 3 & 6 \end{bmatrix}$
Trace $\text{tr } \mathbf{A} = \sum a_{ii}$ \mathbf{A} of square matrix	$\text{tr} \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \\ 7 & 8 & 9 \end{bmatrix} = 1 + 5 + 9 = 15$
Inner product $\mathbf{a} \cdot \mathbf{b} = \mathbf{a}'\mathbf{b} = \sum a_i b_i$ \mathbf{a}, \mathbf{b} of the same order	$\begin{bmatrix} 1 & 2 & 3 \end{bmatrix} \begin{bmatrix} 4 \\ 5 \\ 6 \end{bmatrix} = 4 + 10 + 18 = 32$
Norm of vector $\ \mathbf{a}\ = (\mathbf{a}'\mathbf{a})^{1/2}$ $= (\sum a_i^2)^{1/2}$	$(1^2 + 2^2 + 3^2)^{1/2} = \sqrt{14}$
Norm of matrix $\ \mathbf{A}\ = \text{tr}(\mathbf{A}'\mathbf{A})^{1/2}$ $= (\sum \sum a_{ij}^2)^{1/2}$	$(1^2 + 2^2 + 3^2 + 4^2 + 5^2 + 6^2)^{1/2} = \sqrt{91}$

A matrix \mathbf{A} is called an orthogonal matrix, if \mathbf{A} is nonsingular and $\mathbf{A}^{-1} = \mathbf{A}'$, that is, $\mathbf{AA}' = \mathbf{A}'\mathbf{A} = \mathbf{I}$. The inner products between column vectors in an orthogonal matrix are $\mathbf{a}'_i \mathbf{a}_i = \|a_i\|^2 = 1$ and $\mathbf{a}'_i \mathbf{a}_j = 0 (i \neq j)$.

Let us illustrate using an application of an inverse matrix. Consider the simultaneous equation of the form

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 &= b_1 \\ a_{21}x_1 + a_{22}x_2 &= b_2 \end{aligned}$$

with the condition of $a_{11}a_{22} \neq a_{21}a_{12}$. Let $\mathbf{x} = (x_1, x_2)'$, $\mathbf{b} = (b_1, b_2)'$. Then the above equations are represented as $\mathbf{Ax} = \mathbf{b}$, which leads to $\mathbf{x} = \mathbf{A}^{-1}\mathbf{b}$.

For example, if

$$\mathbf{A} = \begin{bmatrix} 1 & 3 \\ 2 & 4 \end{bmatrix} \text{ and } \mathbf{b} = \begin{bmatrix} -1 \\ 2 \end{bmatrix}$$

then

$$\mathbf{x} = \mathbf{A}^{-1}\mathbf{b} = \frac{1}{-2} \begin{bmatrix} 4 & -3 \\ -2 & 1 \end{bmatrix} \begin{bmatrix} -1 \\ 2 \end{bmatrix} = \begin{bmatrix} 5 \\ -2 \end{bmatrix}$$

Positive-Definite and Positive-Semidefinite Matrices

Let \mathbf{x} be a column vector of order n and \mathbf{A} be a symmetric matrix of order n . Then, $\mathbf{x}'\mathbf{Ax}$ is called a quadratic form in the vector \mathbf{x} .

If $\mathbf{x}'\mathbf{Ax} > 0$ for all \mathbf{x} except for $\mathbf{x} = 0$, the quadratic form is called positive definite. If $\mathbf{x}'\mathbf{Ax} \geq 0$ for all \mathbf{x} and there exists some non-null \mathbf{x} which satisfies $\mathbf{x}'\mathbf{Ax} = 0$, then the quadratic form is called positive semidefinite. If a quadratic form is positive definite or positive semidefinite, the quadratic form is called nonnegative definite. The matrix \mathbf{A} is correspondingly called a positive-definite/positive-semidefinite/nonnegative-definite matrix. If a matrix \mathbf{A} is positive definite, it is represented as $\mathbf{A} > \mathbf{O}$. Similarly, if a matrix \mathbf{A} is positive semidefinite, it is represented as $\mathbf{A} \geq \mathbf{O}$.

For example, let \mathbf{A} be a correlation matrix of order 2, that is,

$$\mathbf{A} = \begin{bmatrix} 1 & r \\ r & 1 \end{bmatrix}$$

The quadratic form $\mathbf{x}'\mathbf{Ax}$ can be written as

$$\begin{aligned} \begin{bmatrix} x_1 & x_2 \end{bmatrix} \begin{bmatrix} 1 & r \\ r & 1 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} &= x_1^2 + 2rx_1x_2 + x_2^2 \\ &= (x_1 + rx_2)^2 + (1 - r^2)x_2^2 \end{aligned}$$

Then, \mathbf{A} is positive definite if $-1 < r < 1$. \mathbf{A} is positive semidefinite if $r = \pm 1$.

\mathbf{A} is usually taken as symmetric. This is because $\mathbf{x}'\mathbf{Ax}$ can be rewritten as $\mathbf{x}'\left[\frac{1}{2}(\mathbf{A} + \mathbf{A}')\right]\mathbf{x}$ and because $\frac{1}{2}(\mathbf{A} + \mathbf{A}')$

is symmetric even if \mathbf{A} is not symmetric. This means that $\mathbf{x}'\mathbf{B}\mathbf{x}$ and $\mathbf{x}'\mathbf{C}\mathbf{x}$ are the same whenever $\mathbf{B} + \mathbf{B}' = \mathbf{C} + \mathbf{C}'$.

If $\mathbf{A} > \mathbf{O}$, then \mathbf{A} is nonsingular and full rank, moreover $\mathbf{A}^{-1} > \mathbf{O}$. If $\mathbf{A} \geq \mathbf{O}$, then \mathbf{A} is singular and not full rank.

Eigenvalue, Spectral and Singular value Decompositions

Eigenvalues and Eigenvectors

A scalar λ is called an eigenvalue of an $n \times n$ matrix \mathbf{A} if there exists a non-null n -dimensional vector \mathbf{x} such that $\mathbf{A}\mathbf{x} = \lambda\mathbf{x}$, or equivalently $(\mathbf{A} - \lambda\mathbf{I})\mathbf{x} = \mathbf{0}$. A vector \mathbf{x} which satisfies this equation is called an eigenvector for the eigenvalue λ . An eigenvector is called a normalized eigenvector if its norm is equal to 1.

Since an eigenvector is a non-null vector, $\mathbf{A} - \lambda\mathbf{I}$ should be singular; hence, its determinant is 0. Then, eigen values of a matrix \mathbf{A} can be obtained as the n roots of the equation $|\mathbf{A} - \lambda\mathbf{I}| = 0$. This equation is called the characteristic equation of a matrix \mathbf{A} .

For example, the eigenvalues of the matrix

$$\mathbf{A} = \begin{bmatrix} 1 & 3 \\ 4 & 2 \end{bmatrix}$$

are obtained by solving

$$\begin{vmatrix} 1 - \lambda & 3 \\ 4 & 2 - \lambda \end{vmatrix} = 0$$

that is,

$$\begin{aligned} (1 - \lambda)(2 - \lambda) - 3 \cdot 4 &= \lambda^2 - 3\lambda - 10 \\ &= (\lambda + 2)(\lambda - 5) \\ &= 0 \end{aligned}$$

That is, $\lambda = -2$ or 5 . Then it follows that $[-3, 3]'$ is an eigenvector for the eigenvalue -2 , and $[-3, -4]'$ for 5 . For example,

$$\begin{bmatrix} 1 & 3 \\ 4 & 2 \end{bmatrix} \begin{bmatrix} -3 \\ 3 \end{bmatrix} = \begin{bmatrix} 6 \\ -6 \end{bmatrix} = -2 \begin{bmatrix} -3 \\ 3 \end{bmatrix}$$

Following are some properties of eigenvalues and eigenvectors. (1) $\mathbf{A}(c\mathbf{x}) = \lambda(c\mathbf{x})$. (2) $\mathbf{A}^k\mathbf{x} = \lambda^k\mathbf{x}$. (3) $\sum \lambda_i = \text{tr}(\mathbf{A})$, λ_i are the i th eigenvalues of a matrix \mathbf{A} . (4) $\prod \lambda_i = |\mathbf{A}|$. (v) If $\mathbf{A}\mathbf{x} = \lambda\mathbf{x}$ and \mathbf{B} is a nonsingular matrix, \mathbf{A} and $\mathbf{B}\mathbf{A}\mathbf{B}^{-1}$ have the same eigenvalues and an eigenvector for $\mathbf{B}\mathbf{A}\mathbf{B}^{-1}$ is $\mathbf{B}\mathbf{x}$.

Spectral Decomposition

Any symmetric matrix \mathbf{A} can be written as

$$\mathbf{A} = \mathbf{V}\mathbf{\Lambda}\mathbf{V}' = \sum \lambda_i \mathbf{v}_i \mathbf{v}_i'$$

where $\mathbf{\Lambda}$ is a diagonal matrix of eigenvalues of \mathbf{A} and \mathbf{V} is an orthogonal matrix whose column vectors are normalized

eigenvectors. This decomposition is called as spectral decomposition.

For example, eigenvalues of a symmetric matrix

$$\mathbf{A} = \begin{bmatrix} 41 & 12 \\ 12 & 34 \end{bmatrix}$$

are 50 and 25. The corresponding eigenvectors are $(4/5, 3/5)'$ and $(-3/5, 4/5)'$. Then, \mathbf{A} can be written as

$$\begin{aligned} \begin{bmatrix} 41 & 12 \\ 12 & 34 \end{bmatrix} &= \begin{bmatrix} 4/5 & -3/5 \\ 3/5 & 4/5 \end{bmatrix} \begin{bmatrix} 50 & 0 \\ 0 & 25 \end{bmatrix} \begin{bmatrix} 4/5 & 3/5 \\ -3/5 & 4/5 \end{bmatrix} \\ &= 50 \begin{bmatrix} 4/5 \\ 3/5 \end{bmatrix} \begin{bmatrix} 4/5 & 3/5 \end{bmatrix} + 25 \begin{bmatrix} -3/5 \\ 4/5 \end{bmatrix} \begin{bmatrix} -3/5 & 4/5 \end{bmatrix} \end{aligned}$$

If \mathbf{A} is a nonsingular symmetric matrix, $\mathbf{A}^r = \mathbf{V}\mathbf{\Lambda}^r\mathbf{V}'$. If \mathbf{A} is a nonsingular symmetric idempotent matrix, eigenvalues of \mathbf{A} should be 0 or 1 since $\mathbf{A}^2 = \mathbf{A}$ leads to $\mathbf{\Lambda}^2 = \mathbf{\Lambda}$.

Singular-Value Decomposition

Let \mathbf{A} be an $n \times p$ matrix. Then $\mathbf{A}'\mathbf{A}$ is a $p \times p$ symmetric matrix and is decomposed as $\mathbf{A}'\mathbf{A} = \mathbf{V}\mathbf{\Lambda}\mathbf{V}'$, where \mathbf{V} is an orthogonal matrix whose columns are eigenvectors of $\mathbf{A}'\mathbf{A}$ and $\mathbf{\Lambda}$ is a diagonal matrix whose diagonal elements are eigenvalues of $\mathbf{A}'\mathbf{A}$.

Similarly, $\mathbf{A}\mathbf{A}'$ is an $n \times n$ symmetric matrix and is decomposed as $\mathbf{A}\mathbf{A}' = \mathbf{U}\mathbf{\Lambda}\mathbf{U}'$, where \mathbf{U} is an orthogonal matrix whose columns are eigenvectors of $\mathbf{A}\mathbf{A}'$ and $\mathbf{\Lambda}$ is a diagonal matrix whose diagonal elements are eigenvalues of $\mathbf{A}\mathbf{A}'$. Nonzero eigenvalues of $\mathbf{A}'\mathbf{A}$ and those of $\mathbf{A}\mathbf{A}'$ are the same.

Using \mathbf{U} , \mathbf{V} and $\mathbf{\Lambda}$, \mathbf{A} can be written as

$$\mathbf{A} = \mathbf{U}\mathbf{\Lambda}^{1/2}\mathbf{V}'$$

This is called as singular-value decomposition of \mathbf{A} .

Projection Matrix

Orthogonal Projector

A square matrix \mathbf{P} is called an orthogonal projector (or projection matrix) if it is both idempotent and symmetric, that is, $\mathbf{P}^2 = \mathbf{P}$ and $\mathbf{P}' = \mathbf{P}$ (Rao and Yanai, 1979).

For a given matrix \mathbf{X} of order $n \times p$ ($n \geq p$) where $\mathbf{X}'\mathbf{X}$ is nonsingular, let $\mathbf{P}_X = \mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'$ and $\mathbf{Q}_X = \mathbf{I} - \mathbf{P}_X$. Then it follows that $\mathbf{P}_X^2 = \mathbf{P}_X$, $\mathbf{Q}_X^2 = \mathbf{Q}_X$ and $\mathbf{P}_X' = \mathbf{P}_X$, $\mathbf{Q}_X' = \mathbf{Q}_X$. Furthermore, it also follows that $\mathbf{P}_X\mathbf{Q}_X = \mathbf{Q}_X\mathbf{P}_X = \mathbf{O}$. Thus, the square matrices \mathbf{P}_X and \mathbf{Q}_X are called orthogonal projectors onto the range spaces $S(\mathbf{X})$ and $S(\mathbf{X})^\perp$.

For example, let $\mathbf{x} = (1, 1, 1)'$. Then,

$$\mathbf{P}_x = \frac{1}{3} \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix} \text{ and } \mathbf{Q}_x = \mathbf{I} - \mathbf{P}_x = \frac{1}{3} \begin{bmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 2 \end{bmatrix}$$

Obviously, $\mathbf{P}_x^2 = \mathbf{P}_x$, $\mathbf{Q}_x^2 = \mathbf{Q}_x$ and $\mathbf{P}_x \mathbf{Q}_x = \mathbf{Q}_x \mathbf{P}_x = \mathbf{O}$ holds true. Let $\mathbf{y} = (y_1, y_2, y_3)'$. It is interesting to note that

$$\mathbf{Q}_x \mathbf{y} = (\mathbf{I} - \mathbf{P}_x) \mathbf{y} = \begin{bmatrix} y_1 - \bar{y} \\ y_2 - \bar{y} \\ y_3 - \bar{y} \end{bmatrix}$$

that is called the deviation score vector from the mean.

An orthogonal projector has following properties:

1. Eigenvalues of \mathbf{P}_X are 1 or 0.
2. $\text{tr}(\mathbf{P}_X) = \text{rank}(\mathbf{P}_X)$.
3. In addition to \mathbf{X} , let \mathbf{Y} be a matrix of order $n \times q$ satisfying $S(\mathbf{X}) = S(\mathbf{Y})$. Then $\mathbf{P}_X = \mathbf{P}_Y$. Thus it follows that an orthogonal projector is uniquely defined onto a given range space $S(\mathbf{X})$ for any choice of \mathbf{X} spanning $V = S(\mathbf{X})$.
4. Let \mathbf{y} be an r -dimensional vector and let \mathbf{b} be a p -dimensional vector. Then, minimizing $\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 = (\mathbf{y} - \mathbf{X}\mathbf{b})'(\mathbf{y} - \mathbf{X}\mathbf{b}) = \mathbf{y}'\mathbf{y} - \mathbf{y}'\mathbf{X}\mathbf{b} - \mathbf{b}'\mathbf{X}'\mathbf{y} + \mathbf{b}'\mathbf{X}'\mathbf{X}\mathbf{b}$, we obtain $\mathbf{b} = (\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}'\mathbf{y}$ which leads to $\|\mathbf{y} - \mathbf{P}_X \mathbf{y}\|^2$. $\mathbf{P}_X \mathbf{y}$ is called the orthogonal projection of \mathbf{y} onto $S(\mathbf{X})$, and thus it follows that,
5. $\|\mathbf{P}_X \mathbf{y}\| \leq \|\mathbf{y}\|$. Equality holds when $\mathbf{y} \in S(\mathbf{X})$.
6. Let \mathbf{X} and \mathbf{Y} be matrices of orders $n \times p$ and $n \times q$ and let \mathbf{P}_X and \mathbf{P}_Y be orthogonal projectors onto $S(\mathbf{X})$ and $S(\mathbf{Y})$, respectively. Then $\mathbf{P}_X \mathbf{P}_Y$ is the orthogonal projector onto $S(\mathbf{X}) \cap S(\mathbf{Y})$, if and only if $\mathbf{P}_X \mathbf{P}_Y = \mathbf{P}_Y \mathbf{P}_X$. Further, $\text{tr}(\mathbf{P}_X \mathbf{P}_Y) \leq \min(\text{rank}(\mathbf{X}), \text{rank}(\mathbf{Y}))$. If $S(\mathbf{Y})$ is a subspace of $S(\mathbf{X})$, then $\mathbf{P}_X \mathbf{P}_Y = \mathbf{P}_Y \mathbf{P}_X = \mathbf{P}_Y$, $(\mathbf{P}_X - \mathbf{P}_Y)^2 = \mathbf{P}_X - \mathbf{P}_Y$ and $\mathbf{P}_X - \mathbf{P}_Y$ is the orthogonal projection matrix onto $S(\mathbf{X}) \cap S(\mathbf{Y})^\perp$.

Generalized Inverse Matrix

Weaker g-Inverse

When \mathbf{A} is singular or rectangular, \mathbf{A}^{-1} does not exist. In this case, a generalized inverse (g-inverse) \mathbf{A}^- can be defined as a matrix satisfying

$$\mathbf{A}\mathbf{A}^-\mathbf{A} = \mathbf{A}$$

(Rao, 1962). In general, \mathbf{A}^- is not unique as shown in the following example. Let

$$\mathbf{A} = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix} \text{ and } \mathbf{A}^- = \begin{bmatrix} a & b \\ c & d \end{bmatrix}$$

Then, $\mathbf{A}\mathbf{A}^-\mathbf{A} = \mathbf{A}$ implies $a + b + c + d = 1$, which leads to

$$\mathbf{A}^- = \begin{bmatrix} a & b \\ c & 1 - a - b - c \end{bmatrix}$$

and \mathbf{A}^- is not unique.

Following are some properties of the weaker g-inverse.

- (1) $(\mathbf{A}\mathbf{A}^-)^2 = \mathbf{A}\mathbf{A}^-$, $(\mathbf{A}^-\mathbf{A})^2 = \mathbf{A}^-\mathbf{A}$.
- (2) $\text{rank}(\mathbf{A}) = \text{rank}(\mathbf{A}\mathbf{A}^-) = \text{tr}(\mathbf{A}\mathbf{A}^-) = \text{rank}(\mathbf{A}^-\mathbf{A}) = \text{tr}(\mathbf{A}^-\mathbf{A})$.
- (3) $\text{rank}(\mathbf{A}^-) \geq \text{rank}(\mathbf{A})$.

- (4) If $\mathbf{A}\mathbf{x} = \mathbf{0}$ then $\mathbf{x} = (\mathbf{I} - \mathbf{A}^-\mathbf{A})\mathbf{z}$ for some \mathbf{z} .
- (5) $\mathbf{A}(\mathbf{A}'\mathbf{A})^-\mathbf{A}'\mathbf{A} = \mathbf{A}$.
- (6) $(\mathbf{A}(\mathbf{A}'\mathbf{A})^-\mathbf{A}'\mathbf{A})' = \mathbf{A}(\mathbf{A}'\mathbf{A})^-\mathbf{A}'\mathbf{A}$.

Using weaker g-inverse, an orthogonal projector when $\mathbf{X}'\mathbf{X}$ is singular can be defined as $\mathbf{P}_X = \mathbf{X}(\mathbf{X}'\mathbf{X})^-\mathbf{X}'$. Property (5) and (6) lead to $\mathbf{P}_X^2 = \mathbf{P}_X$ and $\mathbf{P}_X' = \mathbf{P}_X$ for any choice of $(\mathbf{X}'\mathbf{X})^-$.

Reflexive g-Inverse

If a matrix \mathbf{A}_r^- satisfies both

$$\mathbf{A}\mathbf{A}_r^-\mathbf{A} = \mathbf{A} \text{ and } \mathbf{A}_r^-\mathbf{A}\mathbf{A}_r^- = \mathbf{A}_r^-$$

then \mathbf{A}_r^- is called a reflexive g-inverse of \mathbf{A} . A reflexive g-inverse has a property of $\text{rank}(\mathbf{A}_r^-) = \text{rank}(\mathbf{A})$. For example, if

$$\mathbf{A} = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}$$

then

$$\mathbf{A}_r^- = \begin{bmatrix} a & b \\ c & d \end{bmatrix}$$

where $a + b + c + d = 1$ and $ad = bc$.

Least-Squares g-Inverse

Given a system of linear equations $\mathbf{A}\mathbf{x} = \mathbf{b}$ and $\mathbf{b} \notin S(\mathbf{A})$, then the system is not consistent, that is, this solution does not exist. In such a case, we need a least-squares solution such that $\|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2$ is minimized. The solution is written as $\mathbf{x} = \mathbf{A}_l^-\mathbf{b}$ where \mathbf{A}_l^- satisfies

$$\mathbf{A}\mathbf{A}_l^-\mathbf{A} = \mathbf{A} \text{ and } (\mathbf{A}\mathbf{A}_l^-)' = \mathbf{A}\mathbf{A}_l^-$$

\mathbf{A}_l^- can be written as $(\mathbf{A}'\mathbf{A})^-\mathbf{A}'$ and is called a least-squares g-inverse of \mathbf{A} . It should be noted that $\mathbf{A}\mathbf{A}_l^-$ is the orthogonal projector onto $S(\mathbf{A})$ and thus is unique for any choice of \mathbf{A}_l^- . If \mathbf{A} has column full rank, then $(\mathbf{A}'\mathbf{A})^{-1}\mathbf{A}'$ is one choice of \mathbf{A}_l^- .

For example, if

$$\mathbf{A} = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}$$

then

$$\mathbf{A}_l^- = \begin{bmatrix} a & b \\ 1/2 - a & 1/2 - b \end{bmatrix}$$

Minimum Norm g-Inverse

If $\mathbf{A}\mathbf{x} = \mathbf{b}$ has nonunique solutions, we need a solution with a minimum value of $\|\mathbf{x}\|$. The solution is $\mathbf{x} = \mathbf{A}_m^-\mathbf{b}$, where \mathbf{A}_m^- satisfies

$$\mathbf{A}\mathbf{A}_m^-\mathbf{A} = \mathbf{A} \text{ and } (\mathbf{A}_m^-\mathbf{A})' = \mathbf{A}_m^-\mathbf{A}$$

\mathbf{A}_m^- can be written as $\mathbf{A}'(\mathbf{A}\mathbf{A}')^-$ and is called a minimum norm g-inverse of \mathbf{A} . It should be noted that $\mathbf{A}_m^-\mathbf{A}$ is the

orthogonal projector onto $S(\mathbf{A})$ and thus is unique for any choice of \mathbf{A}_m^- . If \mathbf{A} has row full rank, then $\mathbf{A}'(\mathbf{A}\mathbf{A}')^{-1}$ is one choice of \mathbf{A}_m^- .

For example, if

$$\mathbf{A} = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}$$

then

$$\mathbf{A}_m^- = \begin{bmatrix} a & 1/2 - a \\ c & 1/2 - c \end{bmatrix}$$

Moore–Penrose Inverse

If $\mathbf{A}\mathbf{x} = \mathbf{b}$ has no solution, but has nonunique least-squares solutions, we need a least-squares solution with minimum value of $\|\mathbf{x}\|$. The solution is $\mathbf{x} = \mathbf{A}^+ \mathbf{b}$, where \mathbf{A}^+ satisfies $\mathbf{A}\mathbf{A}^+ \mathbf{A} = \mathbf{A}$, $(\mathbf{A}\mathbf{A}^+)' = \mathbf{A}\mathbf{A}^+$, $(\mathbf{A}^+ \mathbf{A})' = \mathbf{A}^+ \mathbf{A}$, and $\mathbf{A}^+ \mathbf{A} \mathbf{A}^+ = \mathbf{A}^+$.

\mathbf{A}^+ is unique and is called Moore–Penrose inverse of \mathbf{A} (Moore, 1920; Penrose, 1955).

Moore–Penrose inverse of

$$\mathbf{A} = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix} \text{ is } \mathbf{A}^+ = \begin{bmatrix} 1/4 & 1/4 \\ 1/4 & 1/4 \end{bmatrix}$$

Then, for example, the Moore–Penrose solution of

$$\begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix} \mathbf{x} = \begin{bmatrix} 1 \\ 2 \end{bmatrix} \text{ is } \mathbf{x} = \begin{bmatrix} 1/4 & 1/4 \\ 1/4 & 1/4 \end{bmatrix} \begin{bmatrix} 1 \\ 2 \end{bmatrix} = \begin{bmatrix} 3/4 \\ 3/4 \end{bmatrix}$$

Following are some properties of the Moore–Penrose inverse matrix. (1) $\mathbf{A}^+ = \mathbf{A}^{-1}$ if \mathbf{A} is nonsingular. (2) $(\mathbf{A}^+)^+ = \mathbf{A}$. (3) $(\mathbf{A}')^+ = (\mathbf{A}^+)'$. (4) $\mathbf{A}^+ = (\mathbf{A}'\mathbf{A})^{-1} \mathbf{A}'$ if \mathbf{A} is full column rank. (5) $\mathbf{A}^+ = \mathbf{A}'(\mathbf{A}\mathbf{A}')^{-1}$ if \mathbf{A} is full row rank. (6) $\mathbf{A}^+ \mathbf{B} = \mathbf{O} \Leftrightarrow \mathbf{A}'\mathbf{B} = \mathbf{O}$. (7) $\mathbf{A}^+ = \mathbf{A}$ if \mathbf{A} is symmetric and idempotent.

If \mathbf{A} is symmetric and positive semidefinite, the spectral decomposition of \mathbf{A} can be written as $\mathbf{A} = \mathbf{V}\mathbf{\Lambda}\mathbf{V}'$, and the Moore–Penrose inverse matrix can be obtained as

$$\mathbf{A}^+ = \mathbf{V}\mathbf{\Lambda}^{-1}\mathbf{V}'$$

Kronecker Product and Vec Operator

Kronecker Product

Let $\mathbf{A} = [a_{ij}]$ and $\mathbf{B} = [b_{kl}]$ be $n \times m$ and $p \times q$ matrices, respectively. Then the following matrix of orders $np \times mq$ is called the Kronecker product (or direct product) of \mathbf{A} and \mathbf{B} :

$$\mathbf{A} \otimes \mathbf{B} = \begin{bmatrix} a_{11}\mathbf{B} & a_{12}\mathbf{B} & \cdots & a_{1m}\mathbf{B} \\ a_{21}\mathbf{B} & a_{22}\mathbf{B} & \cdots & a_{2m}\mathbf{B} \\ \vdots & \vdots & \cdots & \vdots \\ a_{n1}\mathbf{B} & a_{n2}\mathbf{B} & \cdots & a_{nm}\mathbf{B} \end{bmatrix}$$

Following properties hold for Kronecker products of matrices: (1) $(a\mathbf{A}) \otimes (b\mathbf{B}) = ab(\mathbf{A} \otimes \mathbf{B})$. (2) $(\mathbf{A} \otimes \mathbf{B})' = \mathbf{A}' \otimes \mathbf{B}'$. (3) $(\mathbf{A} \otimes \mathbf{B})(\mathbf{C} \otimes \mathbf{D}) = (\mathbf{A}\mathbf{C} \otimes \mathbf{B}\mathbf{D})$. (4) $\text{rank}(\mathbf{A} \otimes \mathbf{B}) = \text{rank}(\mathbf{A})\text{rank}(\mathbf{B})$.

Vec Operator

Let $\mathbf{A} = [a_1 a_2 \cdots a_m]$ be an $n \times m$ matrix where a_j is the j th column vector of \mathbf{A} . Then $\text{Vec}(\mathbf{A}) = (a_1', a_2', \dots, a_m')'$ is the $nm \times 1$ vector which transforms matrix \mathbf{A} into a vector by stacking all the column vectors in \mathbf{A} one underneath the other. The basic relationship between the Vec operator and the Kronecker product is $\text{Vec}(\mathbf{a}\mathbf{b}') = \mathbf{b} \otimes \mathbf{a}$. Following are some properties of the Vec operator; (1) $\text{tr}(\mathbf{A}\mathbf{B}) = \text{Vec}(\mathbf{A}')' \text{Vec}(\mathbf{B})$. (2) $\text{Vec}(\mathbf{A}\mathbf{B}\mathbf{C}') = (\mathbf{C} \otimes \mathbf{A}) \text{Vec}(\mathbf{B})$. (3) $\text{tr}(\mathbf{A}\mathbf{B}\mathbf{C}\mathbf{D}) = (\text{Vec}(\mathbf{D}))'(\mathbf{A} \otimes \mathbf{C}') \text{Vec}(\mathbf{B}')$.

Matrix Methods in Multivariate Statistical Analysis

Correlation Matrix

Let \mathbf{A} be a raw data matrix of order $n \times p$ where n is the sample size and p is the number of variables. Let $\mathbf{Q} = \mathbf{I} - (1/n) \mathbf{1}\mathbf{1}'$. Then $\mathbf{X} = \mathbf{Q}\mathbf{A}$ is the deviation score matrix from the mean for each of p variables. The covariance matrix of p variables, which is denoted by \mathbf{S} , can be written as $\mathbf{S} = (1/n) \mathbf{X}'\mathbf{X}$. The i th diagonal elements is the variance of i th variable and ij nondiagonal elements are covariances between i th and j th variables.

Let \mathbf{D} be a diagonal matrix whose diagonal elements are equal to \mathbf{S} and let \mathbf{Z} be $\mathbf{X}\mathbf{D}^{-1/2}$. The diagonal elements of $\mathbf{D}^{-1/2}$ are the reciprocal values of standard deviations. Then $\mathbf{R} = (1/n) \mathbf{Z}'\mathbf{Z}$ is the correlation matrix of the p variables. A correlation matrix has following properties: (1) \mathbf{R} is nonnegative definite. (2) $0 \leq |\mathbf{R}| \leq 1$. (3) If $|\mathbf{R}| = 1$ then $\mathbf{R} = \mathbf{I}$.

Principal-component analysis

Principal-component analysis proposed by Hotelling (1933) is one of the most familiar methods of multivariate analysis which uses the spectral decomposition of a correlation coefficient or covariance matrix.

We now show an example of principal-component analysis. Table 3 is the correlation coefficient matrix \mathbf{R} among

Table 3 Correlation matrix among achievement tests

Contribution (%)	63.39	12.88	9.02	7.88	6.26

achievement tests for a university entrance examination (National Center for University Entrance Examinations of Japan, 1982). Eigenvalues of the correlation matrix are 3.197, 0.644, 0.451, 0.394, and 0.313. The sum of these five eigenvalues attains five that is equal to the number of the tests. In the principal-component analysis using a correlation coefficient matrix, eigenvalues are the variances of corresponding principal-component scores. The eigenvectors are computed and multiplied by the square root of the corresponding eigenvalues ($\mathbf{F} = \mathbf{V}\mathbf{\Lambda}^{1/2}$) and are given in **Table 4**. These values are called the principal-component loadings. It can be observed that $\mathbf{R} = \mathbf{F}\mathbf{F}' = \mathbf{V}\mathbf{\Lambda}\mathbf{V}'$.

It follows that the number of principal components with eigenvalues greater than 1 is 1. Thus, most of the variability in the data are explained by the first-principal component. The first principal component seems to be the general achievement abilities measured by means of five common achievement tests, since the principal-component loadings of the five tests range from 0.736 to 0.839, which are considerably high. Other applications of matrix algebra to statistics are factor analysis, regression analysis.

Glossary

Agreement – The measure of agreement intends to quantify the reproducibility of the same variable measured more than once.

Cochran–Mantel–Haenszel procedure – When the association between two discrete variables is affected by a third factor, one should look at the odds ratio of the two variables in separate strata by the third factor. The Cochran–Mantel–Haenszel procedure is used to combine the odds ratios for separate strata into an overall summary estimate.

Continuous variables – A variable is called a continuous variable if it can take on any values within a given interval. There are no gaps in the possible values of the variable.

Discrete ordinal/nominal variables – A discrete variable can take values from a discrete set of numbers. When the numbers reflect only the relative order but not specific numerical values, the discrete variable is called a discrete ordinal variable. If the numbers are used merely to identify categories and the categories have no specific ordering, the discrete variable is called a discrete nominal variable.

Kappa statistic – The Kappa statistic is used to measure the degree of nonrandom agreement between two discrete variables. Here, the nonrandom agreement means that two variables agree more often than expected by chance.

Kendall's tau – The Kendall's tau statistic is a nonparametric measure of association based on the number of concordances and discordances in paired observations. The statistic can be applied to the cases where the variables are continuous and/or discrete ordinal.

Odds ratio – The odds ratio is a basic measure of association in a 2x2 table formed from nominal variables. The odds ratio is defined as the ratio of the odds of an event occurring in one group to the odds of it occurring in another group.

Partial correlation – The partial correlation is a measure that assesses the degree of association between two variables after controlling for other variables. It can be calculated as the Pearson correlation coefficient for the residuals from linear regressions of interested variables on controlled variables.

Rank correlation – The rank correlation coefficient uses the ranks of the data, instead of the actual observed values, to compute a correlation coefficient. It is very useful when there exist extreme values in one or both variables, where the Pearson correlation coefficient will be greatly affected.

Researchers often wish to measure the strength of relationship or association between two variables. A high degree of association indicates that changes in one variable tend to be accompanied by changes in the other, and a low level of association would indicate two variables to be almost independent of each other. There are many indices that characterize the association between two variables. This article divides the indices according to the type of variable we are measuring – namely, whether variables are continuous, discrete ordinal, or discrete nominal. In the following discussion, we assume that a set of n bivariate observations $(x_1, y_1), \dots, (x_n, y_n)$ is measured, and x_i 's and y_i 's can be one of the three variable types. We are interested in assessing the association between X and Y .

Association for Continuous Variables

Consider two continuous variables; for example, the score of a math test versus the score of a science test. The Pearson product–moment correlation coefficient (Pearson, 1896; Fisher, 1915) can be used to measure the degree to which two variables are linearly related, and can be calculated as

$$r = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2 \sum_{i=1}^n (y_i - \bar{y})^2}}$$

where \bar{x} and \bar{y} are the sample means of x_i 's and y_i 's, respectively. The value of r lies between -1 and $+1$. If $r > 0$, then the variables are positively correlated – as x increases (decreases), so does y . If $r < 0$, then the variables are negatively correlated – as x increases (decreases), y tends to decrease (increase). The values of r close to zero mean that there is no linear relationship between the variables; possible reasons can be that (1) the two variables are independent (e.g., knowledge of the math score in no way improves the prediction of the science score), or (2) the two variables have a nonlinear

relationship (e.g., for students with math scores less than 70/100, the higher the math score, the lower the science score; however, for students with math scores greater than 70/100, the higher the math score, the higher the science score).

If we have outliers (i.e., extreme values) in one or both variables, the Pearson correlation coefficient will be greatly affected. For example, consider the situation that a vast majority of students have math scores within the range of 50/100 and 90/100, but there are a few individuals whose scores are extremely low (e.g., 5/100). In that case, the mean math score becomes very small and the value of r becomes quite small, too. There is another alternative. The Spearman rank correlation coefficient (Spearman, 1904) does not use the actual observed data, but the ranks of the data $(r_{x_1}, r_{y_1}), \dots, (r_{x_n}, r_{y_n})$ to compute a correlation coefficient. Here, r_{x_i} is the rank of x_i among x_1, \dots, x_n , and r_{y_i} is the rank of y_i among y_1, \dots, y_n . If tied values exist (e.g., some students have the same score), one can assign the same rank, the average of ranks that originally correspond to these values, to each of the equal values.

In some instances, it is important to assess the degree of association between two variables after controlling for other variables. Researchers may be interested in the relationship between SAT math and science scores after removing the contributions from age and sex. The partial correlation coefficient (Yule, 1897) is a measure that accomplishes this goal. Suppose we are interested in the association between X and Y , but wish to control for other variables Z_1, \dots, Z_p . The partial correlation coefficient is defined to be the Pearson correlation coefficient for the set of n paired derived variables $(e_{x_1}, e_{y_1}), \dots, (e_{x_n}, e_{y_n})$, where e_{x_i} is the residual for the i th individual from the linear regression of X on Z_1, \dots, Z_p , and e_{y_i} is the residual from the linear regression of Y on Z_1, \dots, Z_p . When there is only one Z variable, the partial correlation coefficient is as

$$r_{XY.Z} = \frac{r_{XY} - r_{XZ}r_{YZ}}{\sqrt{(1 - r_{XZ}^2)(1 - r_{YZ}^2)}}$$

where r_{XZ} , r_{XZ} , and r_{YZ} are the Pearson correlation coefficients between X and Y , between X and Z , and between Y and Z , respectively. The correlation between X and Y can be very high, but the partial correlation is low. Students who take the SAT test in their senior year might score higher in both math and science than those who take the test in junior year; therefore, the correlation between SAT math and science scores is high. When we remove this age effect by using the partial correlation, the association might disappear.

Association for Discrete Ordinal Variables

Let x_i 's and y_i 's take values on $1, \dots, I$ and $1, \dots, J$, respectively. Here, the numbers reflect only the relative order, but not specific numerical values. For example, we only

observe students' ranks in math and science tests, but not actual scores. Other than the Spearman rank correlation coefficient we just described, the Kendall's tau rank correlation coefficient (Kendall, 1938) can be used to evaluate the association between X and Y . The Kendall's tau is a nonparametric measure of association based on the number of concordances and discordances in paired observations. Let (x_i, y_i) and (x_j, y_j) be a pair of (bivariate) observations. If $x_j - x_i$ and $y_j - y_i$ have the same sign, we say that the pair is concordant; if they have opposite signs, the pair is discordant. Let C stand for the number of concordant pairs and D stand for the number of discordant pairs. The formula for the Kendall's tau- a is

$$\tau_a = \frac{C - D}{T_0}$$

where $T_0 = n(n-1)/2$ is the total number of pairs of observations. If $\tau_a > 0$, two sets of observations are more likely to be concordant than discordant, and there is a positive relationship between X and Y . $\tau_a < 0$ indicates a negative relationship between X and Y . If there are no tied observations, then $-1 \leq \tau_a \leq +1$. If there are ties, $|\tau_a|$ will be smaller than 1.

When variables have only a few possible values (i.e., I and J are small), the data are typically summarized as an $I \times J$ contingency table with n_{ij} representing the frequency for the i th level of the X variable and the j th level of the Y variable. In our example, this can occur when students are only categorized as excellent, good, average, or poor based on their math and science test results. It should be noted that, now, τ_a no longer lies between -1 and $+1$. Let $n_{i+} = \sum_j n_{ij}$ and $n_{+j} = \sum_i n_{ij}$. A modified version of the Kendall's tau is

$$\tau_b = \frac{C - D}{\sqrt{(T_0 - T_1)(T_0 - T_2)}}$$

where $T_1 = \sum_{i=1}^I n_{i+}(n_{i+} - 1)/2$ is the number of pairs tied on the X variable, and $T_2 = \sum_{j=1}^J n_{+j}(n_{+j} - 1)/2$ is the number of pairs tied on the Y variable. For an $I \times J$ contingency table, C and D can be calculated as

$$C = \sum_{i < i'} \sum_{j < j'} n_{ij} n_{i'j'} \quad \text{and} \quad D = \sum_{i < i'} \sum_{j > j'} n_{ij} n_{i'j'}$$

Association for Discrete Nominal Variables

Here, X and Y are nominal variables, that is, the values of X and Y are used merely to identify categories and the categories have no specific ordering. Contingency tables are usually employed to represent such data. A basic measure of association in a 2×2 table formed from nominal variables (i.e., X and Y both have two categories)

is the odds ratio. The odds ratio is defined as the ratio of the odds of an event occurring in one group to the odds of it occurring in another group. The odds of an event occurring is $p/(1-p)$, where p is the probability of the event. For example, consider the make-up contingency table shown in **Table 1**, with sex as the X variable and classroom participation as the Y variable. The odds ratio of actively participating in classroom for females compared with males is

$$a = \frac{(158/210)/(52/210)}{(176/240)/(64/240)} = \frac{158 \times 64}{176 \times 52} = 1.1$$

Note that the odds ratio can be expressed as the ratio of cross-products of the cell frequencies of the 2×2 table.

The value of the odds ratio falls in $[0, \infty)$. An odds ratio of 1 indicates that the event under study (e.g., active classroom participation) is equally likely in both groups (e.g., females vs males). An odds ratio greater than 1 indicates that the event is more likely in the first group (e.g., females), and an odds ratio less than 1 indicates that the event is less likely in the first group. The odds ratio is invariant under interchange of X and Y variables; that is, the odds ratio of being a female for active classroom participation students compared with occasional classroom participation students is the same as the odds ratio of actively participating in classroom for females compared with males. This property is particularly useful for studies with various sampling schemes. For **Table 1**, one can always obtain the same odds ratio no matter how the study sample is selected. The study can first select 210 females and 240 males and then compare the probability of actively participating in classroom between two genders. Or the study first identifies 334 active classroom participation students and 116 occasional classroom participation students and then determine what proportion of active

classroom participation students are females and what proportion of occasional classroom participation students are females. Or the study can survey 450 students and for each participant we determine his/her gender and classroom participation.

The odds ratio can be transformed to a -1 to 1 scale by converting it to Yule's Q (Yule, 1912):

$$Q = \frac{a-1}{a+1} = \frac{n_{11}n_{22} - n_{12}n_{21}}{n_{11}n_{22} + n_{12}n_{21}}$$

In a situation when the association between X and Y is affected by a third factor, one obvious way is to look at the 2×2 table of X versus Y in separate strata by the third factor. For example, if we are concerned that the class attendance affects the association between sex and the classroom participation, we can calculate the odds ratio for the association between sex and classroom participation in each class attendance group (regular versus irregular). To combine the odds ratios for separate strata into an overall summary estimate, we can use the Cochran–Mantel–Haenszel procedure (Cochran, 1954; Mantel and Haenszel, 1959) that provides a weighted average of the separate odds ratios. The Cochran–Mantel–Haenszel odds ratio is estimated as

$$a_{MH} = \left(\sum_k \frac{n_{11}^{(k)} n_{22}^{(k)}}{n^{(k)}} \right) / \left(\sum_k \frac{n_{12}^{(k)} n_{21}^{(k)}}{n^{(k)}} \right)$$

where k represents the k th 2×2 table (stratum). In our example, suppose the 2×2 tables for the regular class attendance group and the irregular class attendance group are in **Table 2**. Then, the Cochran–Mantel–Haenszel odds ratio can be obtained as

$$a_{MH} = \left(\frac{131 \times 4}{200} + \frac{27 \times 60}{250} \right) / \left(\frac{36 \times 29}{200} + \frac{140 \times 23}{250} \right) = 0.5$$

In some instances, we are interested in quantifying the reproducibility of the same variable measured more than once. This refers to the measure of agreement. As such, agreement is a special case of association. If agreement exists between two occasions, association also will definitely exist, but there can be strong association without strong agreement. One can compute a measure of agreement, when, for example, two raters classify a given

Table 1 Sex vs classroom participation

		Classroom participation		
		Active	Occasional	Total
Sex	Female	158	52	210
	Male	176	64	240
	Total	334	116	450

Table 2 Sex versus classroom participation for each class attendance group

		Classroom participation ^a			Classroom participation ^b		
		Active	Occasional	Total	Active	Occasional	Total
Sex	Female	131	29	160	27	23	50
	Male	36	4	40	140	60	200
	Total	167	33	200	167	83	250

^aRegular class attendance.

^bIrregular class attendance.

student's performance into categories of a discrete variable. Let the X variable represent the results of rater 1 and the Y variable the results of rater 2. The cell frequency n_{ij} is the number of subjects that are classified as the i th category by rater 1 and the j th category by rater 2. One obvious way to quantify the agreement between two raters in the 2×2 case is the observed proportion of agreement

$$p_0 = \frac{n_{11} + n_{22}}{n}$$

The observed agreement proportion is significantly affected by the fact that even if two raters use completely different criteria for calling subjects positive or negative, we would expect agreement about certain subjects solely by chance. For example, if the students are very good, the agreement may be high even if the raters do not agree with each other. One approach to correct for the problem of agreement by chance is to calculate the Kappa statistic (Cohen, 1960)

$$\kappa = \frac{p_0 - p_e}{1 - p_e}$$

where p_e is the expected proportion of agreement purely by chance between two raters. p_e can be calculated under the condition assuming that two raters' results are independent. For example, **Table 3** shows the data for the agreement between two raters. Here, $p_0 = (34 + 248)/318 = 0.89$, and

$$\begin{aligned} p_e &= Pr(\text{rater1} = \text{positive and rater2} = \text{positive}) \\ &\quad + Pr(\text{rater1} = \text{negative and rater2} = \text{negative}) \\ &= \{Pr(\text{rater1} = \text{positive}) \times Pr(\text{rater2} = \text{positive}) \\ &\quad + Pr(\text{rater1} = \text{negative}) \times Pr(\text{rater2} = \text{negative})\} \\ &= \left(\frac{56}{318} \times \frac{48}{318}\right) + \left(\frac{262}{318} \times \frac{270}{318}\right) = 0.73. \end{aligned}$$

Thus, $\kappa = (0.89 - 0.73)/(1 - 0.73) = 0.59$.

The above measures for discrete nominal variables can be generalized to $I \times J$ tables, with $I > 2$ and/or $J > 2$. If one is using odds ratios to describe the associations in an $I \times J$ table, one can start with the number of values, say I and J , for X and Y variables, and then a set of $(I - 1) \times (J - 1)$ odds ratios can be calculated as

$$a_{ij} = \frac{n_{ij}n_{I\bar{j}}}{n_{i\bar{j}}n_{Ij}}$$

where $i = 1, \dots, (I - 1)$ and $j = 1, \dots, (J - 1)$. The Cochran-Mantel-Haenszel procedure can be applied to each of the $(I - 1) \times (J - 1)$ odds ratios. For measuring the reproducibility of a variable with $I > 2$ categories, the Kappa statistic can be obtained by quantifying the agreement on all I categories.

Conclusion

There are different techniques for measuring association for different types of variables. To choose a measure for

Table 3 Rater agreement

		Rater 2		
		Positive	Negative	Total
Rater 1	Positive	34	14	48
	Negative	22	248	270
	Total	56	262	318

two given variables, one can first identify the type of variable for each and follow the recommended measures provided in this article. Caution and appropriate adjustment should be made when there exist factors that can confound the association between variables of interest and when there are several ties as discrete variables involved. It is also important to notice that establishment of a strong association does not imply a causal relationship. Two variables are strongly associated when they tend to change together, whereas causality happens when one variable causes a change in another variable.

Measures of Central Tendency

Glossary

Effect size – A measure of the magnitude of an effect in a study.

Meta-analysis – A quantitative summary of the results from a number of studies.

Statistical power – The probability of avoiding rejecting a true hypothesis.

When trying to summarize a set of data, for example, the reading ability of a class of children, it can be useful to have a measure that tries to represent the middle of the distribution of scores. Such a statistic is described as a measure of central tendency. With such a statistic, it is possible to make comparisons either between groups or over time for the same group, for example, to judge whether there are differences in children's ability to read (i.e., reading ages) when taught by different methods or to judge whether the class has improved over time or after the introduction of a new reading scheme.

The Basic Types

There are three basic measures of central tendency – the mean, the median, and the mode – but, confusingly, the term average is often used as a synonym for all three, despite their definitions being quite different and thus what they refer to being possibly very different. Each measure is described and the relative advantages and disadvantages of each are discussed.

Mean

The mean is the value most normally thought of when the term average is used. It is calculated by summing all the values in the data set, for example, the reading ages, and then dividing that sum by the number of data points which contributed to the sum, for example, the number of children in the class. Parametric statistical tests, such as the independent samples *t*-test, which are designed to look at the difference between central tendencies, for example, in reading age between two classes of children, will compare the means of the different data sets. The mean, or, more precisely, the arithmetic mean, is described below.

Formally, the mean is calculated using the following equation:

$$\text{Mean} = \frac{\sum_{i=1}^n x_i}{n}$$

where x_i is the i th data point and n is the number of data points in the set.

Median

The median is the mid-point, or its equivalent, when the set of data has been put in order of magnitude. When all the data points are different and there is an odd number of them, then the calculation of the median is particularly straightforward. Imagine you have 25 children in a class. You put their reading ages in order, from lowest to highest. The median value is the reading age which has as many below it as above it – in this case, the 13th reading age. When there is an even number of data points, then the median is the arithmetic mean between the highest number in the bottom-half of the data set and the smallest number in the top-half of the data set. Thus, the median of the set of numbers 9, 11, 12, 13 would be 11.5. Nonparametric statistics, such as the Mann–Whitney U test, which are designed to compare central tendencies, often assess whether medians are the same.

Mode

The mode is the most frequently occurring number in the data set.

Distributions and Measures of Dispersion

Before discussing the relative merits of the three measures, it is necessary to mention the distribution of the data and the need for measures to put a measure of central tendency in context. Most well-known parametric tests, such as *t*-tests or analysis of variance (ANOVA), assume that the data in the sample come from a population in which the data are normally distributed. This distribution is sometimes referred to as the bell curve because like a bell it is symmetrical with the most frequent values in the center and the least frequent values at the edges of the distribution. If the data are normally distributed, then the three measures of central tendency will have the same value. However, if the histogram is asymmetrical and has a long tail at one or the other side of the distribution, that is, the data are skewed, then the three measures of central tendency will differ from each other.

An additional feature of a distribution can be how similar the data points are to each other. It is possible to have two sets of data with exactly the same values for a measure of central tendency even though their distributions are very different. As an extreme example, one class of children might all have exactly the same reading age while another might have a wide range of reading ages but have the same mean reading age as the other class. Therefore, a measure of central tendency is not that useful a statistic on its own; it needs to be presented in the context of a measure of dispersion such as the standard deviation.

Characteristics of the Three Measures of Central Tendency

The calculation of the mean entails using the value of every data point. As a consequence, if one or more values, which are extremely high or low, are added to the data set (or they replace existing members of the set), then the value of the mean will move substantially toward such extreme values. For example, if in a class of children, a child with a particularly low reading age relative to the others was added to the class, then the mean reading age for the class would be reduced, possibly markedly. Take a sample of five children with reading ages ranging from 14 years 0 months to 15 years 0 months, and a mean reading age of 14.5 years. If a child with a reading age of 6 years 0 months joins the class and a child with a reading age of 14 years 0 months leaves the class, then the new mean drops to 12.9 years.

The calculation of the median only relies on the order of the data points. Thus, an extreme value in the set would just be treated as the next value in order and its presence merely contributes to finding the position in which the median value lies. Thus, if the lowest reading age in a class was 14 years and that child was replaced by another with a much lower reading age (say 6 years 0 months), then the median reading age for the class would not change.

The mode has a number of disadvantages. First, if all the data points have different values, then there is no unique mode. Second, if two or more values occur with the same frequency, then there may be no single mode; when there are two modes, the term bimodal is used to describe the distribution and when there are more than two modes, the distribution can be described as multimodal. A third disadvantage of the mode is that if all but two data points in the set are different, then the mode is hardly representative of the group. Finally, the most frequently occurring value might be at one extreme of the distribution and once again not represent the whole set well.

Alternative Versions of the Mean

A number of solutions have been proposed to cope with problems which have been identified with the mean.

Two of them – the geometric and harmonic means – involve a different equation to calculate the mean, while two – the trimmed mean and Winsorized mean – involve either removing data or replacing them with other values. Finally, there may be instances where we want particular cases to contribute more to the calculation of the mean. In such instances, we could find a weighted mean.

Geometric mean

The geometric mean entails finding the product of the numbers and then raising that value by the reciprocal of the number of data points which contributed to the product.

Formally, the geometric mean is calculated using the following equation:

$$\text{Geometric Mean} = \sqrt[n]{\left(\prod_{i=1}^n x_i \right)}$$

where x_i is the i th data point and n is the number of data points in the set.

In the set of data 7, 9, 11, 25, the geometric mean = $(7 \times 9 \times 11 \times 25)^{\frac{1}{4}} = 11.47$.

The geometric mean has an advantage over the arithmetic mean in that it is less affected by extreme values in a skewed distribution; in the above example, the arithmetic mean of the four numbers is 13, larger than the geometric mean. In addition, there are instances where we may want to work out a value which is intermediate between two others (to interpolate), and we have good reason to believe that the figures are increasing geometrically. An example would be if we knew the income level in 1 year and the income level for 2 years later and we had good reason to believe that income had risen by a fixed percentage each year. In this instance, the geometric mean between the two income levels would be an accurate estimate of the income in the intervening year. If in the first year, the salary was 10 000 and it went up by 5% per year, then by year 3 it would be 11 025. The geometric mean of these two figures is 10 500, the true value of the salary in the second year, whereas, if we used linear interpolation, which is equivalent to taking the arithmetic mean of the two, we would overestimate the salary in year 2 as 10 512.5.

Harmonic mean

The harmonic mean involves taking the reciprocal of each number. The inverses are summed and the sum is divided into the number of data points which contributed to the sum. (Alternatively, one could sum the inverses, divide the sum by the number of data points and then find the inverse of the result.)

Formally, the harmonic mean can be calculated using the following equation:

$$\text{Harmonic mean} = \frac{n}{\sum_{i=1}^n \frac{1}{x_i}}$$

where x_i is the i th data point and n is the number of data points in the set.

The harmonic mean is used in a number of statistical procedures. An example occurs while finding the statistical power for an independent samples t -test when the samples in the two groups are unequal. The harmonic mean of the two sample sizes is a better estimate of the sample size than the arithmetic mean when calculating the level of power which could be achieved. An example demonstrates that unequal sample sizes in such tests can be inefficient in that they yield a level of power below what the same sample would have if the sample sizes were equal (a balanced design). If the total sample for a study were 60 participants and the two groups being compared had 20 and 40 participants, respectively, then the harmonic mean would be just under 27. Thus, this unbalanced design would only achieve an equivalent level of power to that of a balanced design with a total sample size of 54.

Trimmed mean

Trimming involves placing the data points in order of size and then removing a given percentage from the top and bottom tails of the distribution. The trimmed mean is found by calculating the arithmetic mean of the remaining data. Typical figures for trimming are 5% or 10%, which leads to removing the top and bottom 5% or 10% of values. Clearly this procedure removes extreme values.

Winsorized mean

Winsorizing involves placing the data points in order of size and then rather than deleting the values in each tail, replacing them with the next value in the distribution in that tail. In the data set 1, 3, 7, 9, 11, 25, 36 we could replace the two lowest values with the value next to them and the two highest values with the value next to them, producing the set 7, 7, 7, 9, 11, 11, 11. The Winsorized mean is found by calculating the arithmetic mean of the set of data which remains after Winsorizing.

Weighted mean

The weighted mean involves multiplying each data point in a set by a value which is determined by some characteristic of whatever contributed to the data point. An example should help make that rather vague definition clearer. In meta-analysis, a researcher has a set of effect sizes from a number of studies and wishes to combine them to find an overall effect size to summarize the general trend. The larger the sample which was used in a study, the more accurate the effect size found in that study will be as an estimate of the effect size in the population. Presented with the set of effect sizes, the researcher could weight each one by the sample size for that study. In this way, larger studies would be making a

greater contribution to the mean effect size. To do this, one could multiply each effect size by the sample size for that study, sum each of these results, and then divide the sum by the sum of all the sample sizes.

Formally, the weighted mean is found from the following equation:

$$\text{Weighted mean} = \frac{\sum_{i=1}^n (w_i \times x_i)}{\sum_{i=1}^n w_i}$$

where w_i is the weighting given to the i th data point, x_i is the value of the i th data point and n is the number of data points in the set. Returning to the example of a meta-analysis, w_i could be the sample size in the i th study and x_i the effect size for that study.

Robust estimation

Measures of central tendency such as trimmed or Winsorized means are referred to as robust estimators. Some researchers (e.g., Keselman *et al.*, 2007) argue that inferential statistics based on robust estimators can be preferable, when data are not normally distributed, than either traditional parametric and nonparametric tests, or even permutation tests. They suggest that robust estimators are less likely to lead to the wrong decision over whether to reject the Null Hypothesis. For more detail on robust methods, see Wilcox (2001), Wilcox and Keselman (2003), and Maxwell and Delaney (2004).

Conclusions

It is hoped that among the things which the reader has gleaned from this article is the need to question what is entailed when a value based on a measure of central tendency is presented. If it is stated that the figure is an average, then one would want to know which one.

Measures of Dispersion, Skewness and Kurtosis

Overview

By far, the most common measurements in education and educational research are test scores of some type. These scores are usually considered to be (close enough to) continuous variables, so a major task is to describe the distribution of these scores, and to make inferences concerning them. Researchers use techniques that fall into two broad categories: visual (qualitative) displays and summary (quantitative) statistics. Each has benefits, so a typical analysis will involve both types of techniques.

In many cases, one will want to know whether the distribution of scores can be adequately characterized as having arisen from a particular type of probability distribution, such as the normal – which is the most well-known such distribution. If so, one can easily summarize all of the relevant information with regard to the distribution in the form of a small number of parameters (unknown constants), which can then be estimated from the data. Both visual displays and summary statistics can be used to make decisions about whether the observed data can be assumed to come from (at least approximately) such a known distributional form.

It is common to describe a distribution of scores in terms of its moments. The concept of moments originates from physics and was borrowed to describe mathematical functions known as probability distributions. Measures of dispersion, skewness, and kurtosis are derived from the central moments. The mean is the first central moment – which describes the center of a set of scores. However, to completely describe a distribution of observations, it is insufficient to know just its center. In addition, information is needed to know how the scores are distributed around the center by computing the standard deviation or variance (the second moment about the mean), data symmetry around the center as measured by skewness (the third moment), and whether data are peaked or flat (or even bimodal), indicated by kurtosis (the fourth moment).

Dispersion is the most central concept in statistics. If a set of numbers were all the same, there would be no variability to describe, explain, or relate to other measures; statistical analysis would be irrelevant (unless the results were due to the unlikely event that the sampling units are all the same). Even the term variable is meant to signify that not all observations will be the same; if they are all the same, it is not a variable but a constant. If we had a measure of mathematical reasoning on which we

assigned everyone a score of 82 (and if there were no reason to believe that anyone else existed to whom we would assign a different score), then the measure is not worthy of statistical analysis. We measure people (or other units) in order to discover, describe, and explain variability: How variable are people on some measure, and why are not they all the same?

However, dispersion has related interpretations that are more interesting. Groups with small dispersion are more homogeneous than groups with large dispersion. Thus, if we predicted an (as yet unobserved) person's score using the average of the people we have observed, we expect to be closer to the right answer when the dispersion is small (the group is homogeneous) than when it is large. Thus, dispersion is also a measure of accuracy of prediction (technically, the mean minimizes the sum of squared errors of prediction and is optimal according to some standard criteria).

A related way to think with regard to dispersion is in the two inverse concepts of entropy and information. Entropy is a technical term for a measure of disorder; more variable results indicate greater disorder among a set of numbers. The opposite concept is information: smaller variability indicates that there is more information concerning the likely value of a variable. These concepts can be applied to more than just continuous measures, so they generalize the concept of dispersion to include categorical variables. For example, if people are spread equally between two categories (e.g., male and female), then prediction of the sex of a new person has maximum uncertainty (entropy) and there is minimal information. On the other hand, if 90% of people enjoy eating pasta, and only 10% do not, then information is greater (and uncertainty is less) with regard to whether a person will like pasta. (Note the close relationship to predictability for a new person.) For the remainder of this article, the emphasis is on measures for continuous variables, which is the typical application in applied statistics.

Skewness and kurtosis are not commonly reported or interpreted by educational researchers. They are informative when describing the shape of a distribution, but this information is mostly of interest when comparing a particular set of scores to the normal distribution. These measures are considered prior to performing statistical analyses relying on the data normality assumption. They can be considered diagnostic measures, which identify problematic distribution shapes that require a further intervention – such as a transformation. Although there

are direct statistical tests of normality, they do not indicate how to proceed when non-normality is detected; skewness and kurtosis (as well as graphical methods) often help correct as well as detect non-normality.

In the following sections, a description of commonly used measures of dispersion is presented, focusing on their advantages and limitations. Further, a brief overview of the normal distribution and how skewness and kurtosis statistics are useful descriptors of the shape of educational data that depart from the normal curve is provided. Throughout the article, there are references to two data sets. The US News and World Report College data set (from their 1995 report on American colleges and universities) summarizes information from 1303 institutions on student standardized tests' performance, college tuition and other expenses, acceptance and graduation rates, and faculty characteristics. The Irish data set provides scores of verbal reasoning test as well as parental education and type of school on a sample of 500 Irish schoolchildren who were 11 years old in 1967.

Dispersion

Range and Interquartile Range

Most commonly, the dispersion of a variable is summarized quantitatively in statistics such as range, interquartile range (IQR), variance, and standard deviation. The range is the simplest way to describe a set of test scores: Subtract the smallest (X_{\min}) from the largest (X_{\max}) value. For example, in the following distribution of math scores ordered from the smallest to the highest (71, 75, 79, 86, 90, 94, 96, and 98), the range would be $X_{\max} - X_{\min} = 98 - 71 = 27$. In comparison, in a different distribution of scores (71, 88, 89, 90, 91, 92, 93, and 98), the range would still be the same (27) – as the minimum and the maximum do not change – although scores in between are much closer to each other. While the range of a particular distribution may be useful for learning about the distance between the smallest and the largest values, the drawbacks are evident. Relying on two extreme observations, the range does not take into account the rest of the scores (see **Figure 1**). It is also sensitive to atypical values (outliers) and to the total sample size, increasing with increasing number of observations. Worst of all, the range in a sample of data does not estimate any property of the population, because for most distributions

(including the normal), the population range is infinite. These characteristics make the range nearly useless for inferential purposes.

One way to improve the range statistic is to omit a certain percentage of the tails in a distribution and calculate the difference on the remaining data. It is a common practice to omit 25% of the data at both ends of a distribution and to compute the range for the middle 50% (from 25% to 75%) of the remaining scores. This dispersion-summary statistic is known as the IQR, because it shows how far the first (Q_1) and the third (Q_3) quartiles are from each other (**Figure 1**): $IQR = Q_3 - Q_1$. Q_1 is the median of the lower half of observations, or the 25th percentile, and Q_3 is the median for the top half, or the 75th percentile. For the first set of math scores, the IQR can be computed in the following way:

$$71, \underbrace{75, 79, 86}_{Q_1 = 77}, | \underbrace{90, 94, 96, 98}_{Q_3 = 95} \quad IQR = 95 - 77 = 18$$

Half of the IQR is referred to as the semi-interquartile range or Q . Both Q and IQR have a simple relationship to the standard deviation (σ , described later in this article) in normally distributed data: $Q = 0.6754 \sigma$ or $\sigma \approx 1.5Q$.

Both IQR and Q do a better job than the range in describing the dispersion of data. The IQR of 2.0 from the second distribution of math scores (from a 100-point scale) indicates that there is not much variation in math performance for the middle 50% of students. In comparison, an IQR of 18 describes much more heterogeneous student performance. The drawback of various range statistics, however, is that they rely on a subset of data points to describe variability rather than taking into account all scores.

Standard Deviation and Variance

One approach to using all of the data points would be to compute the average distance between each pair of data points. The further away the scores are from each other, the greater the total dispersion. This method never became popular, partly because of the great amount of computation involved with many data points, and partly because it did not describe a parameter in the population. Other approaches involved finding a center of the set of points (usually the mean or the median), and finding how

Figure 1 Range and interquartile range for the distribution of math scores (71, 75, 79, 86, 90, 94, 96, and 98).

far each of the data points was from the center. Intuitively – if the dispersion was small – most points would be close to the center, and if the dispersion was large, many points would be far from the center. Using the sample mean as the center, for example, one might calculate what are called deviation scores: $x_i = X_i - \bar{X}$. One might think that deriving just the average of these deviation scores could get a measure of dispersion; however, their sum will always equal zero, and their average would also equal zero. There are two obvious ways to overcome this problem: (1) by taking the absolute value of the deviation scores or (2) by squaring them. The second method is more commonly used because of its better computational and inferential properties.

The formula for computing a sample variance is $s^2 = \frac{1}{(n-1)} \sum_{i=1}^n (X_i - \bar{X})^2 = \frac{1}{(n-1)} \sum_{i=1}^n X_i^2$. In this formula, n refers to the sample size. The division by $n - 1$ instead of n is done so that the resulting quantity will be an unbiased estimate of the population variance; $n - 1$ is called the degrees of freedom. The square root of the sample variance – called the sample standard deviation s – is calculated to convert squared deviations back to the original measurement metric.

For the sample of math scores (71, 75, 79, 86, 90, 94, 96, and 98), with $n = 8$ and $\bar{X} = 86.125$, the standard deviation is computed as follows:

$$s = \sqrt{\frac{(71 - 86.125)^2 + (75 - 86.125)^2 + \cdots + (98 - 86.125)^2}{(8 - 1)}} \\ = \sqrt{\frac{718.875}{7}} \approx 10.13$$

The interpretation of the standard deviation's magnitude is relative to the measurement scale as well as the shape of a distribution. A standard deviation of ten might be small or large, depending on how big a 1-unit step is on that measurement scale, and for a particular type of study. A sample of students that has a standard deviation of ten points on an intelligence quotient (IQ) scale is more variable than a sample with a standard deviation of ten points on the Scholastic Aptitude Test (SAT) commonly used in the United States. Note that a sample standard deviation is usually judged to be large or small compared to some hypothetical population value. In the examples just mentioned, IQ scales commonly have population standard deviations of 15, 16, or 20, while SAT scores have a population standard deviation of 100 points. Some authors attempt to compare the standard deviation to the mean, but this only works in special instances where scores have a meaningful zero point.

Knowing the standard deviation of approximately normally distributed data is very informative because a normal distribution is completely determined by its mean

and standard deviation. For instance, for the scores on the Drumcondra Verbal Reasoning Test (DVRT) given to Irish schoolchildren, which approximately follows the normal curve with a mean of 100 and a standard deviation of 15.5 (Figure 2), it can be deduced that about 68% of the DVRT scores fall within the interval $\bar{X} \pm s$, or between 84.5 and 115.5. Further, about 95% of the scores fall within the interval $\bar{X} \pm 2s$, or between 69 and 131. Knowing that a student scored 110 on the DVRT, it can be determined that the score is about $(110 - 100)/15.5 \approx 0.65$ standard deviations above the mean, corresponding to the 74th percentile, so about three-quarters of the students in the sample would score below that student.

Median Absolute Deviation

Because the standard deviation and variance rely on the mean value to compute the average distance of scores away from the center and since the squared differences are used, these measures are sensitive to extreme values – or outliers. An alternative way to summarize variance of data is to use the statistic known as the median absolute deviation (MAD). MAD is a resistant measure of variability as it relies on the median as the estimate of the center of the distribution, and on the absolute difference rather than the squared difference. Initially, one would need to find an absolute value of individual score differences from the median $|X_i - \text{median}|$, order the obtained absolute distances from the lowest to highest, and find the median of the ordered distances. The complete formula for the MAD is $MAD = \text{median}(|X_i - \text{median}|)$. Because the MAD is the median deviation of scores from the overall median, not all observations are equally weighted in this measure of dispersion. The clear advantage of MAD is the avoidance of influence by outliers. However,

Figure 2 Histogram of the verbal reasoning test scores in a sample of 500 Irish schoolchildren (mean ≈ 100 , $s \approx 15.5$), skewness = -0.08 (SE = 0.11), kurtosis = -0.40 (SE = 0.22) with the normal curve superimposed.

it has its own problems: if the distribution is actually normal, there is a loss of efficiency in that it does not make as much use of the information as is available in the data. Therefore, just as the mean is the measure of choice for the center of a distribution that is (at least nearly) normal, so is the standard deviation the measure of choice for the dispersion in that case. Furthermore, for a normal distribution, the mean and standard deviation completely describe the distribution, so that a data set whose underlying distribution is normal can be described in two numbers instead of requiring the complete set of raw data.

For most educational measures, standard deviation or variance are advantageous and sufficient descriptors of data variability. They are easily computed in any statistical package for any number of variables and sample size.

Shape of a Distribution

Visual techniques are especially valuable for learning about a distribution's shape. Generally, one would be interested in whether a distribution of scores resembles the normal curve, which occupies the central niche in statistical theory. Standardized test scores, measures of intelligence (IQ), and depression and anxiety scores (among other constructs educators rely on in their research) are, often, normally distributed because the central limit theorem, which, roughly, states that the sum of independent random measures is approximately normally distributed, especially as the number of items used in constructing a scale increases. Intelligence, aptitude, or psychological measures are commonly represented as a sum of individual items that may be binary (dichotomous) or ordered. While individual items of a test are not normally distributed – based on the central limit theorem – their sum is often well approximated by the normal curve. Due to well-studied mathematical properties of the normal distribution, data normality eases the inferential process and allows applications of various statistical methods relying on the normality assumption (e.g., *t*-tests, analysis of variance (ANOVA)).

Visually, normally distributed data resemble a smooth bell curve rising in the middle and gradually falling at the tails (**Figure 3**). It has a single center (unimodal) – where the mean, median, and mode are located – and it is symmetric. The tails of the distribution are asymptotic, never reaching the value of zero; theoretically, any real number is a possible outcome. Approximately 68% of data are within the interval $\mu \pm \sigma$, and about 95% of data are within the interval $\mu \pm 2\sigma$ (more precisely, 95% are within the interval $\mu \pm 1.96\sigma$, but, in many situations, applied statisticians round 1.96 to 2 when such approximations are acceptable). As mentioned previously, knowing the mean and variance (or standard deviation) is sufficient to completely describe a normal distribution. The sample mean \bar{X} and variance s^2 are unbiased estimators of the population mean μ and variance σ^2 .

The normal curve is theoretically derived, and distributions of real educational data are not as perfect as in their characteristics. The approximation, however, is close enough to assume that data are normally distributed if they possess certain distributional properties. There are several ways to evaluate whether a particular distribution resembles a normal curve. Graphically, data are often summarized in a histogram with an overlying normal curve (as in **Figure 2**) to allow comparisons between the two. The number of modes is the first property to be noticed. In the example of the DVRT scores, there is only a single peak around the value of 100. In comparison, the distribution of the in-state tuition variable (**Figure 4**) is bimodal; there are two peaks occurring around the values of \$2000 and \$10 000. Based on the histogram, there appear to be two clusters of colleges – one with low, and the other with higher, tuition rates. Upon closer examination, the lower cluster corresponds to public colleges and the higher cluster represents private institutions. In that case, a normal distribution is not a good approximation of such data, and it may be advantageous to analyze each college type separately.

Next, the examination proceeds to two properties of data – skewness and kurtosis – that can be used for two

Figure 3 The normal distribution with corresponding areas under the curve.

purposes. Each is a valid descriptive statistic in its own right, helping to define the shape of the distribution of data. However, most often, these statistics are used for another purpose: to determine whether or not a data set is (close enough to) normally distributed so that common methods of analysis can be used.

Skewness

Symmetry is another property of normally distributed data that should be examined. From a graph, one can evaluate whether approximately the same shape and the same data frequency are observed on both sides of a distribution. In the DVRT scores example (Figure 2), the histogram of the scores is symmetric, while the in-state college-tuition histogram (Figure 4) is not. There is a mathematical measure of symmetry known as skewness. The theoretical normal distribution is perfectly symmetrical, and its corresponding skewness statistic is zero. When a distribution has an elongated right tail, it is positively skewed (i.e., it has a positive skewness statistic; e.g., percentage of alumni who donate to their colleges in Figure 5). Conversely, when the left tail is long, the

distribution is negatively skewed (e.g., percentage of applicants accepted by 1291 colleges in Figure 6).

The skewness is computed as follows:

$$skewness = \frac{\sum_1^n (X_i - \bar{X})^3}{(n-1)s^3}$$

Conceptually, the skewness statistic measures cubed standardized differences between individual scores and the mean, keeping the sign of the difference (unlike the case with the standard deviation). If there is a particular number of observations a certain distance below the mean and an equal number is the same distance above the mean, their contributions to skewness will be canceled out, resulting in the skewness of zero. An imbalance of scores around the mean will lead to either large positive or large negative skewness. To decide whether a particular distribution of scores is strongly (significantly) skewed in comparison to the normal, one can perform a hypothesis test. The null hypothesis states that the distribution under consideration has a skewness of zero. To test the hypothesis, the obtained value of the skew statistic is divided by its standard error:

$$SE(skewness) = \sqrt{\frac{6n(n-1)}{(n-2)(n+1)(n+3)}}$$

and the obtained ratio is compared to the critical value of 1.96. Note that for large sample size n , the standard error is approximately the square root of $6/n$. If an absolute value of the ratio is smaller than 1.96, the null hypothesis is retained. If it is larger than 1.96, it can be concluded that the skewness is significantly different from zero and the data may require a transformation. Because the standard error largely depends on the sample size, it is harder to detect skewness in small samples, while, too often, large samples will produce statistically significant results even when the departure from normality is small. Therefore, the skewness statistic should be supported by graphical evidence of nonsymmetry.

Although a symmetric distribution has a skewness of zero, the converse is not true – that is, a distribution can

Figure 4 Histogram of the in-state tuition variable measured across 1272 colleges, skewness = 0.43 (SE = 0.07), kurtosis = -0.75 (SE = 0.14).

Figure 5 Histogram of the percentage of alumni who donate to their colleges for 1088 institutions, skewness = 0.77 (SE = 0.07), kurtosis = 0.32 (SE = 0.15) with the superimposed normal curve that has the same mean and standard deviation.

Figure 6 Histogram of the percentage of accepted applicants variable from 1291 colleges, skewness = -1.11 (SE = 0.07), kurtosis = 1.61 (SE = 0.14) with the superimposed normal curve with the same mean and standard deviation.

have a skewness of zero and not be symmetric. This would not be common, but one should remember that checking skewness is a shortcut and not a perfect test of symmetry. A symmetric distribution will have zero moments around the mean for all odd powers, not just the third (i.e., skewness).

The most common transformations of variables with a skewed distribution involve moving the stretched tail closer to the center by some mathematical manipulations, such as taking the square root, inverse, logarithm, or taking scores to a power. While some skewed distributions can be normalized using such mathematical transformations, others cannot or should not be. For instance, nothing can be done to multimodal or J-shaped distributions, or variables with pronounced floor or ceiling effects. There is a breadth of statistical methods available for working with such data. Such solutions are preferable to using methods relying on the normality assumption when it cannot be met.

Kurtosis

The last property of data that is to be discussed to assess whether they come from a normal distribution is kurtosis, which evaluates (approximately) how peaked or how flat a distribution is. The fourth moment of the normal curve has a value of 3, and the general formula is

$$\text{kurtosis} = \frac{\sum_{i=1}^n (X_i - \bar{X})^4}{(n-1)s^4} - 3$$

A kurtosis of zero is obtained for scores from a normal distribution (since we subtract the value of 3 in the kurtosis formula). A negative kurtosis corresponds to a platykurtic, or wide, distribution with more extreme scores than expected in the normal. Such a distribution would be wider and thicker in the tails. The t distribution, for example, has negative kurtosis. A positive kurtosis represents a leptokurtic – or narrow – distribution, with fewer scores in the tails than in the normal (e.g., to some degree in the distribution of the percentage of accepted applicants in **Figure 5**; to a greater degree in the percentage of applicants who donate to their colleges in **Figure 6**).

Even more extreme values of kurtosis are found in multimodal distributions and, in particular, in bimodal distributions (**Figure 4**). Bimodal distributions have a very large proportion of their observations a large distance from the middle of the distribution, even more so than the flat distributions often used to illustrate high values of kurtosis, and have more negative values of kurtosis than other distributions with heavy tails such as the t .

While positive or negative values of the kurtosis statistic may indicate the direction of nonnormality, they have

to be formally tested to see if the difference between the observed kurtosis and that expected in the normal curve is statistically significant. Similar to the test of skewness, one would divide the kurtosis by its standard error:

$$SE(\text{kurtosis}) = 2 \times SE(\text{skewness}) \sqrt{\frac{n^2 - 1}{(n-3)(n+5)}}.$$

Note that for large sample size n , the quantity under the radical is near 1, and the standard error of the kurtosis is approximately twice the size of the standard error of the skewness. An absolute value of the ratio that is larger than 1.96 would indicate a shape of a distribution statistically different from normal. Again – as with any test of a null hypothesis – one must consider sample size when interpreting the result: a large sample size might detect very small departures from normality.

There are no simple transformations available for normalizing a distribution with extreme values of kurtosis, but this is not of much concern to most researchers. The skewness properties of a distribution are much more important for selecting appropriate statistical tests than its kurtosis. Due to the central limit theorem, repeated sampling from a highly kurtotic distribution (e.g. uniform or bimodal) will approximate the normal with sample sizes as low as five or ten. However, to achieve the same results with a skewed distribution, much larger samples are needed.

While the third and the fourth central moments (skewness and kurtosis) are informative in comparing distributional properties to those of the normal curve, there are other approaches to evaluate normality. The most commonly used graphical tests summarize data in forms of quantile–quantile (Q–Q) plots or the normal probability plots. There are also a number of formal statistical tests that measure how closely a given data set resembles the normal (e.g., Kolmogorov–Smirnov and Shapiro–Wilk tests, among others), but these do not provide information about why normality is violated or how to correct it.

Conclusion

Dispersion is the most basic concept in statistics; in fact, the field of statistics is often defined as the study of variation in data. A normal distribution, the most commonly encountered distribution in many fields of statistics, can be completely described by its location (mean) and dispersion (standard deviation or variance). Higher-order moments about the mean – such as skewness and kurtosis – can be used in their own right to help describe a distribution, or as the means to an end: detecting departures from normality.

Glossary

***d* family** – This is a set of effect-size indices which calculates the difference between the means of two groups (e.g., experimental vs. control, pre-test vs. post-test) standardized or not by an estimate of the within-study standard deviation. These effect indices are specially indicated for primary studies where subjects are assigned to different groups or conditions.

Effect size – This quantifies the extent to which the phenomenon investigated is present in the study results, regardless of the sample size and the result of the statistical tests.

Fixed-effects model – In meta-analysis, a fixed-effects model is a statistical model in which it is assumed that the effect sizes calculated from a set of primary studies estimate the same population effect size. The only error source is that produced by sampling error.

Meta-analysis – This is a research methodology that aims to quantitatively integrate the results of a set of primary studies about a given topic in order to determine the state of the art on that topic.

Mixed-effects model – When a meta-analysis aims to search for moderator variables that can explain the variability in the effect-size estimates, a mixed-effects model is applied where the studies compose a random variable and the moderator variables are fixed variables.

Moderator variable – This is a differential characteristic of the primary studies that is coded in a meta-analysis with the purpose of examining its possible relationship with the study results. The moderator variables can be substantive, methodological, or extrinsic.

Publication bias – This occurs when, in a given research field, the publication of research results depends on its direction. Meta-analyses that have included only published studies may suffer a bias in their effect estimates.

***r* family** – This is a set of effect-size indices that groups all of the correlation coefficients between two variables (e.g., Pearson correlation coefficient, biserial correlation, and point-biserial correlation). These effect indices are specially indicated for correlational studies.

Random-effects model – In meta-analysis, a random-effects model is a statistical model in which the effect size obtained from each primary study estimates a different population effect size and, as a consequence, the effect estimates have two error sources: sampling error and variability among the population effect sizes.

Standardized mean difference – This is an effect-size index from the *d* family that reflects the magnitude of the differences between the means of two groups (e.g., experimental vs. control) divided by an estimate of the within-study standard deviation.

Introduction

From the second-half of the last century, research in education has grown exponentially. From this explosion of evidence has arisen a need to develop systematic and objective methods for accumulating the scientific knowledge obtained from the primary studies. With this aim, meta-analysis has emerged as a methodology that is able to quantitatively combine the results of a set of primary investigations on a given topic in order to figure out the state of the art on that topic. Unlike traditional reviews, which are qualitative or narrative and characterized by subjectivity, meta-analysis considers the review of the past research to be a scientific enterprise that, like primary research, should be guided by the principles of objectivity, systematization, and replicability. The main characteristic of meta-analysis is the use of statistical methods to quantitatively integrate the results of the studies.

Although its origins go back to the decade of the 1930s, it was not until the end of the 1970s that G. V. Glass (1976) coined the term meta-analysis to refer to this research methodology. Meta-analysis began to gain popularity in psychology with the pioneer meta-analyses of M. L. Smith and G. V. Glass on the effectiveness of psychotherapy, R. Rosenthal and D. B. Rubin on the effects of interpersonal expectancy on the research results, and with the meta-analytic validity generalization approach of F. L. Schmidt and J. E. Hunter. In education, the pioneer meta-analysis was that carried out by M. L. Smith and G. V. Glass on the effects of class size on the attitudes and academic performance of students. Since then, meta-analysis has been

applied in education in many different research areas such as the effects of instructional programs on student performance, gender differences in academic performance, predictors of academic performance, or the validity of screening and diagnostic instruments in detecting psychoeducational problems.

The phases in developing a meta-analysis, an overview of the effect-size indices, the statistical models most usually applied in meta-analysis, an example to illustrate the meta-analytic calculations, and some final remarks are presented in this article. Throughout the article, the meta-analysis of Ginns (2006) on the instructional effects of spatial and temporal contiguity of learning materials is used as an example.

Phases in a Meta-Analysis

To carry out a meta-analysis, the researcher must follow several steps: (1) formulating the problem, (2) searching for the literature, (3) coding the studies, (4) statistical analysis and interpretation, and (5) publication of the meta-analysis.

Given below are the details of the steps to be followed:

1. *Formulating the problem.* As in any primary research, the first step in a meta-analysis consists of defining its purpose, which generally will be to examine the relationship between two or more (psychological and/or educational) constructs. In this phase, the researcher must define the constructs implied, both theoretically and empirically, as well as review the existing theoretical models and formulate the concrete objectives of the review.

In Ginns' (2006) meta-analysis, the purpose was to review the experimental studies about the effects of instructional learning by manipulating the spatial or temporal contiguity of disparate but related elements of information. In this meta-analysis, Ginns (2006) tried to determine the extent to which the effects of instructional learning could be generalized across different students, learning materials, and testing contexts.

2. *Searching for the literature.* Once the objectives are formulated, the next step involves defining the selection criteria that the empirical studies must fulfill and carrying out as complete a literature search as possible. The selection criteria will depend on the purpose of the meta-analysis, but there are several criteria that should be present in any meta-analysis, such as specifying: (1) the time period of the studies, (2) the design type in the empirical studies, and (3) the language in which the study was written. In order to search for the studies that fulfill the selection criteria, several searching strategies should be used, combining both formal

and informal search procedures. Formal procedures consist of consulting electronic bibliographic databases (e.g., ERIC, PsycINFO), relevant journals, bibliographic reference volumes, and references in studies. Informal sources enable us to find fugitive literature, that is, papers that have not been published (e.g., dissertations, technical reports, papers presented at congresses) or papers published in journals or books that cannot be found through formal sources.

In Ginns' (2006) example, in order to be included in the meta-analysis the studies had to apply a between-group design with random assignment of the subjects to the groups and to report statistical data about the effects of manipulating spatial or temporal contiguity of instructional materials. The search strategy included consulting the ERIC and PsycINFO databases, Science Citation Index, and the references of the papers located.

3. *Coding of studies.* The main purpose of a meta-analysis is to explain the variability found in the study results on a given topic by examining the influence of differential characteristics among them. To accomplish this objective, the studies are subjected to a coding process in which relevant moderator variables of the results are identified. Moderator variables are study characteristics that can influence the outcome. Although the moderator variables to be coded depend on the purpose of the meta-analysis, it is usual to classify them into three main clusters: methodological, substantive, and extrinsic characteristics.

Methodological characteristics refer to those related with the methodology of the study, such as the design type or the amount of attrition in the groups. Substantive characteristics are those directly related with the research topic investigated in the meta-analysis, as well as with the sociodemographic characteristics of the sample. In Ginns' (2006) example, some of the substantive characteristics coded were the type of split-attention effect (spatial or temporal contiguity), the field of study (science, or engineering/technical), and the educational level of the sample. Finally, extrinsic variables are those characteristics that should not be related with the study results because they have nothing to do with the research enterprise. Examples of this type of variables are the publication year of the study, the publication source (published or unpublished), and characteristics of the researchers (e.g., gender, affiliation). In addition to the moderator variables, the main result of each study is summarized by calculating an effect-size estimate.

4. *Statistical analysis and interpretation.* In a meta-analysis a mean effect is calculated from the set of effect sizes, as well as a confidence interval and an assessment of the extent of heterogeneity exhibited by them around the mean effect. If there is more heterogeneity than sampling error can explain, then additional analyses

are done to search for moderator variables of the effect estimates.

5. *Publication.* The final step in a meta-analysis is its publication. The sections that a meta-analytic report should include are basically the same as those in a primary study (introduction, method, results, and discussion), but in the method section, the epigraphs are not the same as those in primary research: literature search, coding of studies, effect-size index, and statistical analysis. A meta-analysis that is to be published must include all the information needed for its potential replication by another researcher.

Effect-Size Indices

An essential requisite to carry out a meta-analysis is to obtain a quantitative index that summarizes the results of each study. Moreover, the quantitative indices obtained from the studies must be in the same metric for their quantitative integration to be possible. The best strategy for accomplishing this requisite is to calculate an effect-size index, which represents the extent to which the phenomenon of interest is manifested in the study results. There are many different effect-sizes indices, the choice depending on the design type of the studies and on the nature of the variables involved in the studies (continuous, dichotomous, etc.). In education, the most frequently applied effect sizes in meta-analysis are those grouped into two families: the *d* family, for experimental and quasi-experimental designs, and the *r* family, for correlational studies (Hedges and Olkin, 1985).

The *d* Family

When the study design involves assigning subjects to different groups (e.g., experimental vs. control) and the dependent variable is continuous, the most appropriate family of effect sizes is the *d* family, which includes a set of effect sizes defined as the difference between two means divided by a within-group standard deviation. When the study comprises a two-group design, the effect size most usually applied from the *d* family is the standardized mean difference, which is calculated by

$$d = c(m) \frac{\bar{y}_E - \bar{y}_C}{S} \quad [1]$$

\bar{y}_E and \bar{y}_C being the estimated means of the experimental and control groups, respectively, S being the estimated pooled within-study standard deviation obtained by

$$S = \sqrt{\frac{(n_E - 1)S_E^2 + (n_C - 1)S_C^2}{n_E + n_C - 2}} \quad [2]$$

with n_E and n_C being the sample sizes of both groups, and S_E^2 and S_C^2 the respective estimated variances. When the study design includes a control group, Glass *et al.* (1981)

proposed dividing the mean difference by the standard deviation of the control group, S_C , instead of S , because sometimes applying a treatment can alter the variability in the scores of the dependent variable. But provided homoscedasticity is met, S is a more efficient estimate of population standard deviation. The $c(m)$ factor is needed to correct a positive bias of the *d* index for small sample sizes and is obtained by

$$c(m) = 1 - \frac{3}{4(n_E + n_C) - 9} \quad [3]$$

The *d* index is an estimate of the population standardized mean difference, $\delta = (\mu_E - \mu_C)/\sigma$, with μ_E and μ_C being the population means of the experimental and control groups, and σ being the common population standard deviation. As an estimate of δ , the *d* index is approximately normally distributed with mean δ and sampling variance σ_d^2 , which is estimated by

$$\hat{\sigma}_d^2 = \frac{n_E + n_C}{n_E n_C} + \frac{d^2}{2(n_E + n_C)} \quad [4]$$

Dividing the difference in mean by the standard deviation of the groups in [1] makes it possible to homogenize the metric of studies that have used different dependent variables to measure the outcome.

Several adaptations of the *d* index have been devised for studies that include pre-test and post-test measures for only one group or for a two-group design (Morris, 2008). Other effect-size indices that can be applied when the design is composed of two groups and the dependent variable is dichotomous, or has been dichotomized, are the difference between the success (or failure) proportions for the experimental and the control groups (or risk difference), the rate between both proportions (or risk ratio), and the odds ratio (Deeks and Altman, 2001).

The *r* Family

When the study results are obtained by applying a correlational design, that is, studies where the researcher does not manipulate independent variables, the most appropriate effect size consists of calculating a correlation coefficient. Depending on the type of variables involved in the relationship (continuous, dichotomous, dichotomized, ordinal variables, etc.), different correlation coefficients are used as the effect size: Pearson correlation coefficient, point-biserial correlation, Spearman's rank order correlation, etc. All of these correlation coefficients make up the *r* family of effect-size indices.

As the correlation coefficients do not always follow a normal distribution, their transformation into the Fisher's *Z* has been proposed to normalize the sampling distribution and to stabilize the variance. Thus, it is very usual in meta-analysis to transform the correlation coefficients, *r*,

into Fisher's Z by means of

$$Z_r = \frac{1}{2} \ln \left(\frac{1+r}{1-r} \right) \quad [5]$$

where \ln is the natural logarithm. However, there is no clear consensus on this topic, and some authors advise against transforming correlation coefficients into Fisher's Z (e.g., Hunter and Schmidt, 2004). The sampling variance of Fisher's Z is a function of the sample size, N :

$$\sigma_{Z_r}^2 = \frac{1}{N-3} \quad [6]$$

Sometimes, a meta-analysis integrates experimental and correlational studies, so that the meta-analyst has been able to obtain a d index from the experimental studies and an r index from the correlational ones. In order to put all of the effect sizes into the same metric, formulas have been devised to transform them. Thus, to transform a d index into an r index, or vice versa, we can apply the equation

$$r = \frac{d}{\sqrt{d^2 + 4}} \quad [7]$$

There are also formulas for transforming an odds ratio into a d index (Sánchez-Meca *et al.*, 2003). Thus, most of the effect-size indices usually applied in meta-analysis can be transformed into one another.

Statistical Procedures in Meta-Analysis

Once we have coded a set of moderator variables in the studies and we have calculated an effect-size estimate from each of them, the statistical analyses carried out in a meta-analysis aim to answer several questions: (1) What is the average effect magnitude throughout the studies? (2) Is the average effect size statistically significant? (3) Is there heterogeneity among the effect-size estimates? and (4) If the effect estimates are not homogeneous, which of the moderator variables can explain the variability?

There is currently a consensus on the convenience of applying weighting procedures in meta-analysis in order to give more weight to the effect sizes obtained from the studies with a lesser sampling variance, that is, with a larger sample size. Depending on the assumptions made by the meta-analyst, the weighting procedures can be approached from different statistical models, basically, fixed-, random-, and mixed-effects models.

Calculating an Average Effect Size

The statistical analyses in a meta-analysis are guided by a statistical model that must be previously assumed. The main task of the statistical model is to establish the properties of

the effect-size population from which the individual effect-size estimates have been selected. To accomplish the first purpose in a meta-analysis, that is, to calculate an average effect size, two statistical models can be assumed: the fixed- and the random-effects models.

Suppose there are k independent empirical studies about a given topic and T_i is the effect-size estimate obtained in the i th study (here T_i refers to any of the different effect-size indices presented above, both from the d and the r families.) In a fixed-effects model, it is assumed that all of the effect-size estimates come from a population with a common parametric effect size, θ , and as a consequence the only error source is that produced by sampling error, e_i . Thus, the model can be formulated as $T_i = \theta + e_i$, the sampling errors, e_i , being normally distributed with mean 0 and sampling variance σ_i^2 , $e_i \sim N(0, \sigma_i^2)$. Therefore, the effect-size estimates, T_i , are also normally distributed with mean θ and sampling variance σ_i^2 , $T_i \sim N(\theta, \sigma_i^2)$.

In a random-effects model, it is assumed that the effect-size estimates, T_i , estimate different population effect sizes, θ_i , that is, $T_i = \theta_i + e_i$, and θ_i pertains to a distribution of parametric effect sizes with mean μ and variance τ^2 , usually called between-studies variance. The parametric effect sizes can be modeled as $\theta_i = \mu + \varepsilon_i$, ε_i being the errors of the parameters around its mean, μ . Therefore, the random-effects model is formulated as $T_i = \mu + \varepsilon_i + e_i$. Assuming normality, T_i has as mean μ and variance $\tau^2 + \sigma_i^2$, $T_i \sim N(\mu, \tau^2 + \sigma_i^2)$. Thus, the fixed-effects model can be considered a particular case of the random-effects model when the between-studies variance is zero ($\tau^2 = 0$) and, as a consequence, all the parametric effect sizes are equal ($\theta_1 = \theta_2 = \dots = \theta_{i..} = \theta = \mu$).

To calculate an average effect size from a set of studies, each effect-size estimate must be weighted by its precision. Both in a fixed- and a random-effects model, the uniformly minimum variance unbiased estimator (UMVUE) of the average effect size, μ , is that obtained by weighting each effect-size estimate by its inverse variance:

$$T_{\text{UMVUE}} = \frac{\sum_{i=1}^k w_i T_i}{\sum_{i=1}^k w_i} \quad [8]$$

where w_i is the optimal weight for the i th study and, depending on the statistical model assumed, it is defined as $w_i^{\text{FE}} = 1/\sigma_i^2$ or as $w_i^{\text{RE}} = 1/(\tau^2 + \sigma_i^2)$, for the fixed- and the random-effects models, respectively.

In practice, the optimal weights cannot be used, because the within-study sampling variances, σ_i^2 , and the between-studies variance, τ^2 , are unknown. For each effect-size index, formulas have been devised to estimate σ_i^2 and τ^2 . Thus, the estimated weights are defined as $\hat{w}_i^{\text{FE}} = 1/\hat{\sigma}_i^2$ and $\hat{w}_i^{\text{RE}} = 1/(\hat{\tau}^2 + \hat{\sigma}_i^2)$ for fixed- and random-effects models, respectively. (Another option

consists of simply weighting each effect-size estimate by its sample size (Hunter and Schmidt, 2004).) Here $\hat{\sigma}_i^2$ is the estimated within-study sampling variance for the i th study (e.g., eqn [4] for the d index), and $\hat{\tau}^2$ can be calculated by applying one of the different estimators of the between-studies variance proposed in the meta-analytic literature. The τ^2 estimator most usually applied in meta-analysis is that based on the moments method:

$$\hat{\tau}^2 = \frac{Q - (k - 1)}{c} \quad [9]$$

where k is the number of studies, Q is a heterogeneity statistic defined in eqn [17], and c is obtained by:

$$c = \sum_{i=1}^k \hat{w}_i^{\text{FE}} - \frac{\sum_{i=1}^k (\hat{w}_i^{\text{FE}})^2}{\sum_{i=1}^k \hat{w}_i^{\text{FE}}} \quad [10]$$

When $Q < (k - 1)$, then $\hat{\tau}^2$ is negative and must be truncated to zero. Other τ^2 estimators can be consulted in Viechtbauer (2005).

With the respective estimated variances, the population effect size, μ , is then estimated by:

$$T_{\text{FE}} = \frac{\sum_{i=1}^k \hat{w}_i^{\text{FE}} T_i}{\sum_{i=1}^k \hat{w}_i^{\text{FE}}} \quad [11]$$

$$T_{\text{RE}} = \frac{\sum_{i=1}^k \hat{w}_i^{\text{RE}} T_i}{\sum_{i=1}^k \hat{w}_i^{\text{RE}}} \quad [12]$$

for fixed- and random-effects models, respectively. When a fixed-effects model is assumed, T_{FE} is approximately normally distributed and its sampling variance defined as:

$$V(T_{\text{FE}}) = 1 / \sum_{i=1}^k \hat{w}_i^{\text{FE}} \quad [13]$$

Thus, a confidence interval for the average effect size can be obtained by (cf. e.g., Cooper *et al.* 2009):

$$T_{\text{FE}} \pm z_{\alpha/2} \sqrt{V(T_{\text{FE}})} \quad [14]$$

where $z_{\alpha/2}$ is the $100(\alpha/2)$ percentile of the standard normal distribution and α is a significance level.

Under a random-effects model, a better approach for obtaining a confidence interval for the overall effect size consists of assuming a Student t reference distribution with $k - 1$ degrees of freedom, instead of the standard normal distribution:

$$T_{\text{RE}} \pm t_{k-1, \alpha/2} \sqrt{V(T_{\text{RE}})} \quad [15]$$

where $t_{k-1, \alpha/2}$ is the $100(\alpha/2)$ percentile of the Student t distribution with $k - 1$ degrees of freedom, and $V(T_{\text{RE}})$ is an estimate of the sampling variance for T_{RE} , which is obtained by (cf. Sánchez-Meca and Marín-Martínez, 2008)

$$V(T_{\text{RE}}) = \frac{\sum_{i=1}^k \hat{w}_i^{\text{RE}} (T_i - T_{\text{RE}})^2}{(k - 1) \sum_{i=1}^k \hat{w}_i^{\text{RE}}} \quad [16]$$

Alternative approaches to those presented in eqns [14] and [15] have been proposed (cf. e.g., Sánchez-Meca and Marín-Martínez, 2008).

Assessing Heterogeneity in the Effect Sizes

One of the main purposes of meta-analysis is to examine the variability among the effect-size estimates. If the heterogeneity exhibited by the effect estimates can be explained by random sampling alone, then the average effect size represents a good summary of the general trend in the study results. If, on the contrary, the effect estimates reflect true heterogeneity, that is, variability among the effect sizes due to differential characteristics of the studies, then the average effect size does not represent the effect estimates, and the meta-analyst should search for moderator variables that can explain (at least part of) the heterogeneity.

To assess whether a set k of independent effect estimates show true heterogeneity, the most usual strategy in meta-analysis is to apply the heterogeneity Q statistic which, under the null hypothesis of homogeneity ($H_0: \theta_1 = \theta_2 = \dots = \theta_k = \mu$), follows a chi-square distribution with $k - 1$ degrees of freedom, and is obtained through

$$Q = \sum_{i=1}^k \hat{w}_i^{\text{FE}} (T_i - T_{\text{FE}})^2 \quad [17]$$

By assuming a given significance level, α , it is possible to make a decision about whether the effect-size estimates are homogeneous or not. However, due to the low statistical power of the Q statistic when the number of studies is small (about $k < 30$), it is advisable to complement this statistical test with the I^2 index, which quantifies the extent of true heterogeneity present in the studies (Higgins and Thompson, 2002):

$$I^2 = \frac{Q - (k - 1)}{Q} \times 100 \quad [18]$$

When $Q < (k - 1)$, then I^2 is truncated to zero. Values of $I^2 = 25\%$, 50% , and 75% can be interpreted as reflecting small, medium, and high heterogeneity among the effect sizes, respectively.

Analyzing the Influence of Moderator Variables

If the effect-size estimates exhibit more heterogeneity than random sampling can explain, then the meta-analyst has to search for moderator variables that can account for that heterogeneity. In order to accomplish this objective, linear models are assumed, where the effect-size estimates are taken as the dependent variable, and moderator variables coded in the studies act as predictor variables. The most appropriate statistical model for dealing with this task is the mixed-effects model, in which the studies (or the effect-size estimates) are taken as random-effects variables, and study-level moderator variables are taken as fixed-effects variables. When the moderator variable is categorical (e.g., type of population), an analysis of variance by weighted least squares is applied, whereas regression models are used to assess the influence of continuous moderator variables (e.g., duration of the program, mean age in the sample).

In matrix notation the regression coefficient vector of the model is estimated by $\hat{\beta} = (\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}\mathbf{X}'\mathbf{W}\mathbf{T}$, where \mathbf{X} is a $k \times p$ design matrix that includes p predictors, \mathbf{T} is the effect-sizes vector, with range k , and \mathbf{W} is a $k \times k$ diagonal weighting matrix, with the element in the diagonal defined as the estimated weights: $\hat{w}_i^{\text{ME}} = 1/(\hat{\tau}_{\text{ME}}^2 + \hat{\sigma}_i^2)$. The between-studies variance, $\hat{\tau}_{\text{ME}}^2$, is estimated by:

$$\hat{\tau}_{\text{ME}}^2 = \frac{Q_E - (k - p)}{\text{tr}\mathbf{W} - \text{tr}[\mathbf{W}\mathbf{X}(\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}\mathbf{X}'\mathbf{W}]} \quad [19]$$

where tr represents the trace of a matrix and Q_E is the weighted residual sum of squares of the regression model, that is defined as:

$$Q_E = \mathbf{T}'\mathbf{W}\mathbf{T} \quad [20]$$

Model misspecification can be tested by using the Q_E statistic. Under the null hypothesis that the regression model is not misspecified ($H_0: \mathbf{T} = \mathbf{X}\beta$), the Q_E statistic follows a chi-square distribution with $k - p - 1$ degrees of freedom.

Once the model misspecification has been examined, the significance of the full regression model is tested with the weighted regression sum of squares, Q_R , which is obtained by

$$Q_R = \hat{\beta}'\hat{\Sigma}_{\beta}\hat{\beta} \quad [21]$$

where $\hat{\Sigma}_{\beta}$ is the estimated variance–covariance matrix of the coefficient vector. Under the null hypothesis of no relationship between the predictors and the effect estimates ($H_0: \beta = \mathbf{0}$), the Q_R statistic follows a chi-square distribution with p degrees of freedom. Finally, the partialized effect of each predictor can be assessed by applying a Z test for its regression coefficient, $\hat{\beta}_j$:

$$Z = \hat{\beta}_j / \hat{\sigma}_{\hat{\beta}_j} \quad [22]$$

where $\hat{\sigma}_{\hat{\beta}_j}$ is the estimated standard error of the regression coefficient, taken from the j th diagonal element of $\hat{\Sigma}_{\beta}$. Under the null hypothesis of no effect for the predictor, Z follows a standard normal distribution.

An Example

To illustrate the meta-analytic calculations presented in the previous epigraph, we have selected part of the data reported in Ginns' (2006) meta-analysis about the instructional effects of manipulating the temporal contiguity of learning materials. The effect-size index was the standardized mean difference, d_b , defined as the difference between the means of the experimental (temporally integrated materials) and control (non-integrated condition) groups divided by the pooled standard deviation (see eqn [1]). **Table 1** shows the meta-analytic database for this example, which includes information relative to 13 studies. (As Ginns' (2006) meta-analysis did not report the sample size for each study, we have invented them in order to carry out the statistical analyses. Therefore, our results have only illustrative purposes and do not coincide with those presented in Ginns (2006).) The moderator variables reported in **Table 1** were the publication year, the sample size, n_i (here we assumed that the sample sizes of the experimental and control groups were equal in each study, i.e., $n_{Ei} = n_{Ci} = n_i$), the type of testing (group vs. individual), and the field of the study (science vs. engineering/technical). **Table 1** also shows the estimated within-study variance, $\hat{\sigma}_i^2$, for each study, obtained by eqn [4], and the estimated fixed- and random-effects weights: $\hat{w}_i^{\text{FE}} = 1/\hat{\sigma}_i^2$ and $\hat{w}_i^{\text{RE}} = 1/(\hat{\tau}^2 + \hat{\sigma}_i^2)$, respectively (**Figure 1**).

A graphical representation typical in meta-analysis is the forest plot, which consists of showing each individual estimated effect size and its 95% confidence interval and, at the bottom of the graph, the average effect size for all of the studies. This graph helps to capture the general trend and the variability of the effect sizes.

Table 2 presents the average effect size obtained with the 13 effect estimates and the 95% confidence interval for the fixed- and the random-effects models. Thus, assuming a fixed-effects model, the average effect size was $d_+ = 0.768$ (by applying eqn [11]), with confidence limits, 0.637 and 0.899 (by applying eqn [14]). Assuming a random-effects model, the average effect size was $d_+ = 0.888$ (with eqn [12]), with confidence limits, 0.574 and 1.202 (with eqn [15]). In both cases, the average effect size was statistically significant, as the null effect was not contained in the confidence intervals. The confidence interval for the random-effects model was larger (interval amplitude: 0.628) than that of the fixed-effects model (interval amplitude: 0.262), due to the fact that the random-effects model assumes that the effect sizes of the studies estimate different population effect sizes.

Table 1 Meta-analytic dataset of the effects of the temporal contiguity of instructional materials on student performance

Study	Year	Testing	Broad field of the study	n_i	d_i	$\hat{\sigma}_i^2$	\hat{w}_i^{FE}	\hat{w}_i^{RE}
1	1999	Group	Science	12	2.06	0.2551	3.9204	2.4352

13	2000	Individual	Engineering/Technical	48	0.33	0.0422	23.6777	5.0556

n_i – sample size for each group of the i th study, the total sample size of the study being $N_i = 2xn_i$; d_i – standardized mean difference for the i th study; $\hat{\sigma}_i^2$ – estimated within-study variance for the i th study (calculated by eqn [4]); $\hat{w}_i^{FE} = 1/\hat{\sigma}_i^2$ is the estimated fixed-effects weight for the i th study; and $\hat{w}_i^{RE} = 1/(\hat{\tau}^2 + \hat{\sigma}_i^2)$ is the estimated random-effects weight for the i th study.

From Ginns P. (2006). Integrating information: A meta-analysis of the spatial contiguity and temporal contiguity effects. *Learning and Instruction* 16, 511–525.

Figure 1 Forest plot of the d indices for 13 studies on the temporal contiguity effects. The variances were calculated by eqn [4], the 95% confidence intervals by eqn [11], and the mean effect size from a fixed-effects model by eqn [13].

Table 2 Summary results of calculating an average effect size and a 95% confidence interval from the fixed- and random-effects models

Statistical model	k	d_+	$V(d_+)$	95% C. I.	
				d_l	d_u
Fixed-effects	13	0.768	0.0045	0.637	0.899
Random-effects	13	0.888	0.0208	0.574	1.202

K – number of studies; d_+ – average effect size calculated by eqns [11] and [12] for the fixed- and random-effects models, respectively; $V(d_+)$ – sampling variance of d_+ , calculated by eqns [13] and [16], respectively; d_l and d_u – lower and upper confidence limits of the 95% confidence interval around d_+ , calculated by eqns [14] and [15], respectively.

The heterogeneity Q statistic, calculated by eqn [17], was statistically significant [$Q(12) = 43.584$, $p < .001$]; the I^2 index, by eqn [18], was of high magnitude: $I^2 = 72.5\%$; and the between-studies variance was $\hat{\tau}^2 = 0.155$ (by eqn [9]). Therefore, the set of effect sizes exhibited more variability than random sampling can explain and, as a consequence, the search for moderator variables is justified. In order to do this, analyses of variance and regression models by weighted least squares and assuming a mixed-effects model can be applied.

Table 3 presents an example of how to analyze the influence of a qualitative moderator variable on the effect size by applying an analysis of variance. The moderator

Table 3 Analysis of variance by weighted least squares and assuming a mixed-effects model of the d indices as a function of the field of the study

Field of study	k	d_+	95% C. I.		Q_{wj}	DF	p
			d_l	d_u			
Science	5	0.947	0.499	1.395	6.336	4	.175
Engineering/ technology	8	0.523	0.523	1.205	6.762	7	.454
$Q_B(1) = 0.084, p = .772$							
$Q_W(11) = 13.098, p = .287$							

K – number of studies for each category; d_+ – average effect size for each category; d_l and d_u – lower and upper confidence limits of the 95% confidence interval around d_+ for each category; Q_{wj} – within-category homogeneity Q statistic which, under the null hypothesis of within-category homogeneity, follows a chi-square distribution with $k - 1$ degrees of freedom (DF); Q_W – global within-category homogeneity Q statistic which, under the null hypothesis of global within-category homogeneity, follows a chi-square distribution with $k - c$ degrees of freedom, c being the number of categories; Q_B – between-categories Q statistic which, under the null hypothesis of equal average effect sizes, follows a chi-square distribution with $c - 1$ degrees of freedom; and p – probability level of the corresponding Q statistic.

Table 4 Simple regression models by weighted least squares and assuming a mixed-effects model of the d indices as a function of the publication year and sample size

Predictor variable	k	$\hat{\beta}_j$	$SE(\hat{\beta}_j)$	$Q_R(DF)$	p	$Q_E(DF)$	p	R^2
Year	13	0.018	0.024	0.604(1)	.437	12.771(11)	.308	.045
Sample size	13	-0.027	0.008	11.886(1)	< .001	10.630(11)	.475	.528

K – number of studies for each category; $\hat{\beta}_j$ – unstandardized regression coefficient for each predictor variable; $SE(\hat{\beta}_j)$ – standard error of $\hat{\beta}_j$; Q_R – weighted regression sum of squares (by eqn [21]); DF – degrees of freedom; Q_E – weighted residual sum of squares (by eqn [20]); p – probability level of the corresponding Q statistic; and R^2 – proportion of variance accounted for.

variable is the field of study (science vs. engineering/technical). The average effect sizes for both categories were very similar: $d_+ = 0.947$ for science and $d_+ = 0.864$ for engineering/technical, leading to a nonstatistically significant result for the Q_B statistic, which assesses whether the mean effect sizes are equal [$Q_B(1) = 0.084, p = .772$]. The Q_W statistic reveals that the model is not misspecified [$Q_W(11) = 13.098, p = .287$]. Therefore, the field of study does not seem to be a moderator variable of the effect sizes.

Finally, **Table 4** presents the results of two simple regression analyses, one for the publication year and the other for the sample size. The sample size exhibited a statistically significant relationship with the effect sizes, as the Q_R statistic reveals [$Q_R(1) = 11.886, p < 0.001$], whereas publication year did not reach statistical significance [$Q_R(1) = 0.604, p = 0.437$]. Moreover, the regression model for sample size was not misspecified [$Q_E(11) = 10.630, p = 0.475$]. Hence, it seems that the effect sizes were associated with sample sizes.

Concluding Remarks

In this article, we have focused on the meta-analytic approach most usually applied in education, which

consists of calculating an effect-size index from each study and putting it into relation with study-level moderator variables that can explain the variability usually exhibited by the effect sizes. In addition to the statistical methods presented here, other analytic approaches have been devised in the meta-analytic literature. Thus, Hunter and Schmidt (2004) proposed the validity generalization approach with the purpose of integrating a set of validity coefficients of a given measurement instrument obtained from applying the instrument to different samples and contexts. In this meta-analytic approach, also named psychometric meta-analysis, different statistical and measurement artifacts that affect the empirical validity coefficients can be corrected, such as the measurement error, the range restriction, or the effects of dichotomizing variables. In the same vein, Vacha-Haase (1998) has proposed the meta-analytic reliability generalization approach, with the aim of integrating a set of reliability coefficients obtained in successive applications of the same measurement instrument, and assessing whether the reliability of the test scores can be generalized across different samples, contexts, and applications. Other specific approaches devised in meta-analysis enable us to apply multivariate models to integrate a set of dependent effect-size estimates obtained from each study (cf. e.g., Becker, 2000), or to integrate correlation matrices

obtained from the studies in order to meta-analyze factor analyses (e.g., Becker, 1996).

Without a doubt, meta-analysis is contributing in education to better accumulate the scientific evidence disseminated across studies by applying the same scientific rigor demanded of primary research. Meta-analysis has become a necessary link between the past research and the future research efforts in any field. The main characteristic of this research methodology is the use of statistical methods to integrate study results but, as it is a relatively new field, more methodological work is needed in order to adapt the current meta-analytic techniques to address more complex problems.

Missing Data

C A W Glas, University of Twente, Enschede, The Netherlands

© 2010 Elsevier Ltd. All rights reserved.

In educational research, missing data create various problems. On the most elementary level, missing data reduce the sample size which decreases the precision of estimates and the power of statistical tests. From a practical perspective, missing data are often a nuisance because many computational procedures prefer complete data sets. Therefore, statistical packages either only accept complete data sets, or provide tools for creating a complete data set through the imputation of missing values. In both cases, action is required. Finally, missing data may cause a threat to the validity of the inferences. If, for a random part of a sample, some pages in a questionnaire are missing due to an error of the printer, it may not pose a serious threat to validity. However, if teachers are inclined to exclude low-ability students from an educational survey because their assessment results are too embarrassing, inferences will obviously be biased. Rubin (1976) described and named a number of types of mechanisms causing missing data and investigated their consequences for statistical analyses. This topic is addressed first; subsequently, a number of ways of dealing with missing data are discussed.

Missing Data Mechanisms

The mechanism that caused the missing data is mostly unknown to the statistician analyzing the data. To shed some light on the mechanism, the statistician can compare the outcomes obtained from analyses under various assumptions. An important aid for making such assumptions is the following classification of the possible mechanisms causing the missing data. The mechanisms causing the incompleteness are characterized according to their degree of randomness.

Missing Completely at Random

The least problematic is the case where the missingness is unrelated to both observed data and unobserved data. An example is the above-mentioned problem of missing pages in a questionnaire due to an error of the printer. This missingness clearly does not depend on any observed or unobserved responses. In such a situation, the missing data are called missing completely at random (MCAR). To make this more formal, consider variables (say socioeconomic status, intelligence quotient, item responses, and gender) labeled $k = 1, \dots, M$ and cases (students,

teachers, etc.) labeled $i = 1, \dots, N$. Further, for the potential observation, y_{ik} , we define a missing data indicator

$$d_{ik} = \begin{cases} 0 & \text{if } y_{ik} \text{ was not observed} \\ 1 & \text{if } y_{ik} \text{ was observed.} \end{cases}$$

MCAR entails that d_{ik} and y_{ik} are independent, and the methods for handling missing data discussed below can be directly applied without further assumptions.

Missing at Random

A slightly more complicated case arises when the missing data indicators d_{ik} are independent of the missing data, but depend on the observed data. Therefore, if \mathbf{D} is a matrix of all missing data indicators d_{ik} , and \mathbf{Y}_{obs} and \mathbf{Y}_{miss} stand for the observed and missing part of the data, respectively, then

$$p(\mathbf{D} | \mathbf{Y}_{obs}, \mathbf{Y}_{miss}, \phi, \mathbf{X}) = p(\mathbf{D} | \mathbf{Y}_{obs}, \phi, \mathbf{X}),$$

where \mathbf{X} stands for a set of covariates that might be observed and ϕ is a vector of the parameters of the distribution of \mathbf{D} .

As an example, consider the well-known case of missing at random (MAR) that arises in educational assessment in two-stage testing (Lord, 1980). In this testing, students are first presented a so-called routing test. If the number-correct score on the routing test is above some cutoff point, a student is administered a difficult follow-up test, and if the number-correct score is below the cutoff point, an easy follow-up test is presented. The missing data are the responses of the students above the cutoff point on the easy follow-up test and those below the cutoff point on the difficult follow-up test. These missing data are MAR because the missing data indicators are completely determined by the observations, that is, by the number-correct scores on the routing test. The consequences are discussed in the next section.

Ignorable Missingness

Suppose that we want to estimate a parameter or a vector of parameters θ . It seems plausible to do this using the data that are actually available. For instance, one may use maximum likelihood (ML) estimation and maximize the likelihood

$$P(\mathbf{Y}_{obs} | \theta, \mathbf{X}) = \prod_{i=1}^N \prod_{k=1}^M p(y_{ik} | \theta, \mathbf{x}_i)^{d_{ik}} \quad [1]$$

as a function θ . The density $p(y_{ik} | \theta, \mathbf{x}_i)$ may, for instance, be a normal density associated with the regression of y_{ik} on \mathbf{x}_i ,

and θ contains regression coefficients and variance parameters. The density can also be a probability associated with a discrete item response y_{ik} and θ contains the item and person parameters of an item response theory (IRT) model (Lord, 1980). Rubin (1976) shows that estimation procedures that maximize the likelihood given by eqn [1] are justified if ignorability holds. Rubin's so-called ignorability principle entails that ignoring the missing data mechanism in frequentist inferences based on the likelihood function and Bayesian inferences based on the posterior distribution does not create bias if two conditions are met. The first condition is that the missing data should be MAR and the second is that the parameters of interest, say θ , should be distinct from the parameters of the missing data process ϕ . In a frequentist framework, distinctness means that there are no functional dependencies in the parameter space of θ and ϕ (e.g., θ and ϕ should not be identical). In a Bayesian framework, distinctness means that the prior distributions of θ and ϕ are independent. If the conditions MAR and distinctness are satisfied, the missing data process is ignorable in statistical inferences, which means that using the distribution $P(Y_{obs}|\theta, X)$ instead of $P(Y_{obs}, Y_{mis}|\theta, \phi, X)$ and thus ignoring the process that caused the missing data does not produce bias in the parameter estimates.

Applied to the two-stage testing design presented above, this leads to the interesting conclusion that the estimates of θ obtained from the items administered to the examinees are not influenced by the fact that the high-ability students are presented a difficult test and the low-ability students an easy test.

Nonignorable Missingness

When ignorability is violated, missingness should not be ignored. It may be that the MAR assumption is violated because the probability of missingness is related to values that are missing themselves. An example is that respondents in a survey may fail to answer questions of a sensitive nature (e.g., about income, sexual habits, or weight) because their values on these variables are too extreme. Alternatively, distinctness may be violated because the parameters of interest θ and the parameters governing the missing data process ϕ are highly correlated or identical, for instance, when students have the opportunity to choose the items they respond to and do so based on an ability parameter θ that is the target of estimation. If ignorability does not hold, the process causing the missing data must be taken into account in the estimation procedure. This is further clarified below.

Missing Data Techniques

Many taxonomies of methods for dealing with missing data are available (see, e.g., Little and Rubin, 1987 or Buhi *et al.*, 2008); however, none of them is completely

satisfactory. In the present article, we use an imperfect grouping of methods for dealing with missing data into three categories: deletion procedures, single imputation procedures, and model-based estimation and multiple imputations procedures.

Deletion Procedures

The most used deletion procedures are listwise and pairwise deletion. Listwise deletion (or casewise deletion) entails excluding cases with missing values for any variable. For example, all students that fail to respond to one or more items in an assessment are removed from the analysis. In pairwise deletion (or available case analysis), all available data for each variable and each pair of variables are used to compute such statistics as means, variances, and covariances. Though deletion procedures are readily available in multipurpose statistical packages (such as Self-Propelled Semi-Submersible (SPSS), STATA, and SAS), such procedures are not very recommendable. The first problem with this approach is that it reduces the sample size, which results in a decrease of precision of estimates and power of tests. Further, both methods are based on the assumption of MCAR. If the assumption is violated, the inferences are probably misleading. General purpose statistical software packages, such as SPSS, support testing this assumption using Little's chi-square test (Little and Rubin, 1987). A special problem arises with pairwise deletion when covariances are estimated. Since the estimates are based on differing numbers of observations, the resulting covariance matrix may not be proper, that is, it may not be positive definite. In that case, techniques based on the covariance matrix, such as factor analysis and structural equation modeling, become infeasible, or at least highly problematic. Further, correlation matrices derived from covariance matrices estimated using pairwise deletion can be outside the range of -1.0 to 1.0 .

Single Imputation Procedures

Imputation methods are those where the missing data are filled in to create a complete data matrix that can be analyzed using standard methods. Single imputation procedures are those where one value for a missing data element is filled in without defining an explicit model for the partially missing data. A method that is often used is mean substitution where missing values are replaced with the variable mean score. However, an observation y_{ik} can both depend on an effect of variable k and a case-specific effect i . Therefore, more advanced versions of the method take both the effects of the variables and the case-specific effects on the observations y_{ik} into account. An example in educational assessment is Kelly's method for filling in missing student grades. This method estimates standardization weights for subject grades such that the difficulty of subjects and the strictness of possible raters are corrected for.

These standardization weights are then used to approximate a student's grade in a subject which would be obtained in the ideal situation when all students took all subjects, and all subjects were marked by the same examiners (Kelly, 1976).

In hot-deck imputation, missing values are replaced with observed values from a respondent with the same or a very close response pattern on a group of matching variables. Finally, in regression imputation, the missing value for a targeted variable is estimated using the regression of the target variable on all other variables or a subset of all other variables.

One of the problems with all single imputation methods is that the filled-in observations are treated as actual observations in subsequent analysis. However, the filled-in values are estimates, which have standard errors. Multiple imputations can be used to take the uncertainty about the estimates into account. This is one of the topics of the next section.

Model-Based Estimation and Multiple Imputations

It has already been discussed above that if ignorability holds, a model can be estimated only using the observed data. ML estimation (maximization of $P(Y_{obs}|\theta, X)$ as a function of θ) and Bayesian estimation (estimation of the posterior distribution $P(\theta|Y_{obs}, X)$), both with an observed data likelihood as in eqn [1], are especially suited for this approach. For instance, most software for the analysis of educational assessments with IRT modeling uses this approach; examples are Bilog-MG (Zimowski *et al.*, 1996) and Conquest (Wu *et al.*, 1997). However, in many cases, ML and Bayesian methods based on eqn [1] may become quite complicated. Solutions in these cases are found in the Expectation-Maximization (EM) algorithm and the Markov chain Monte Carlo (MCMC) method with data augmentation.

For advanced practitioners, these are valuable tools for computing estimates for complex models with missing data. However, they are also the basis for the generally used procedure of multiple imputation. In multiple imputation (Rubin, 1987, 1996), a number of draws of the missing data (say, between three and six) are made from the posterior distribution of the missing data, given the observed data $p(Y_{mis}|Y_{obs}, \theta)$. This distribution is available through the EM algorithm or the MCMC algorithm, which are both outlined below. Subsequently, for each of these draws, estimates are computed using standard software for complete data, and, finally, the results are averaged over the draws. Accordingly, uncertainty about missing values is taken into account. Multiple imputation for variables following the multivariate normal distribution is supported by programs as NORM (Schafer, 1999), S-plus 6 for Windows (2006), and SAS 8.1 (Yuan, 2000). Multiple imputations of categorical variables can be

created using the log-linear model (Schafer 1997), which is implemented in the missing data library of S-plus (2006). For data sets containing a combination of categorical and continuous variables, Schafer (1997) proposed a general location model, which is a combination of a log-linear and a multivariate normal model. This model is also implemented in the missing data library of S-plus.

In a generalized linear model (such as linear regression, logistic regression, or hierarchical linear modeling), missing data can both appear in dependent and independent variables. When creating imputations for missing values of the independent variables, all information, including the available values for the dependent variables, should be used. (see, e.g., Allison, 2002). If the dependent variables are disregarded, the estimated regression coefficients are biased toward zero. Imputation of missing values for the dependent variable is somewhat more complicated. Von Hippel (2007) proposes a procedure wherein all cases are used to determine the imputations, but where the cases with imputed values on the dependent variable are excluded for the subsequent analyses.

The analysis of categorical variables using log-linear models is based on data organized in frequency tables. An important limitation of imputation of missing values for categorical variables using log-linear models is that the number of variables that can be handled is limited by the size and dimensionality of these frequency tables. Therefore, Vermunt *et al.* (2008) proposed to use latent class modeling as a tool for density estimation in the presence of missing data. In this application, the number of latent classes is chosen to be large because the interest is not in coming up with an interpretable set of latent classes underlying the data, but in accurately estimating the higher-order moments of the data. The procedure is implemented in the software program Latent GOLD.

Multiple imputations can be generated by many procedures (e.g., Latent GOLD uses a nonparametric bootstrap procedure). However, the EM algorithm and the MCMC algorithm are the two most common procedures. They are outlined as follows.

The EM algorithm (Dempster *et al.*, 1977) is a general iterative algorithm for ML estimation in incomplete data problems. It handles missing data as follows. First, given some initial estimate, say θ^* , the posterior distribution of the missing values $p(Y_{mis}|Y_{obs}, \theta^*)$ is computed. In many instances, it also suffices to compute the expectation of the sufficient statistic for θ ; therefore, in these cases, this implies computing an actual value for the missing data. Second, we compute ML estimates of θ using the likelihood $p(Y_{obs}, Y_{mis}|\theta)$ averaged over the distribution of the missing data $p(Y_{mis}, Y_{obs}|\theta^*)$ computed in the previous step. Again, in many instances, it suffices to fill in the expectation of the sufficient statistics for θ , after which averaging is not necessary. Finally, these two steps (the E-step and the M-step) are repeated until the process converges.

An alternative approach to the ML framework with the EM algorithm is a Bayesian approach using the MCMC algorithm with data augmentation. In a Bayesian approach, data and parameters have the same status: they are both seen as random variables. Data augmentation (Tanner and Wong, 1987) entails adding random variables to the model to simplify computations. A much-used version of the MCMC algorithm is the Gibbs sampler (Gelfand *et al.*, 1990; Gelman *et al.*, 1995; Geman and Geman, 1984). For the Gibbs sampler, the variables are partitioned into a number of subsets and samples are drawn from the posterior distribution of each subset, given previous draws. Applied to the present problem, in its simplest versions, the algorithm creates a sample from $p(Y_{mis}, \theta | Y_{obs})$ by alternately sampling from $p(\theta | Y_{mis}, Y_{obs})$ and $p(Y_{mis} | Y_{obs}, \theta)$. After choosing starting values for θ , the algorithm must first make a number of so-called burn-in iterations to move θ into the region where the posterior distribution has its main probability mass. Subsequently, every draw comes from the targeted posterior.

Modeling the Missing Data Process

If the missing data process is not ignorable, the process causing the missing data must be taken into account. This is done by considering both the observed data Y_{obs} and the missing data indicator D as random variables, with distributions with parameters θ and φ , respectively. The likelihood can be written as

$$p(Y_{obs}, D | \theta, \phi, X) = p(Y_{obs} | D, \theta, X) p(D | \phi, X), \quad [2]$$

where X are observed covariates. Note that these covariates influence missingness through the distribution $p(D | \phi, X)$. Well-known examples are found in the general class of stochastic censoring and self-selection models by Heckman (1976, 1979). Heckman initially developed the procedure for continuous data. Applications to categorical data are, for instance, found in Fay (1986), O'Muircheartaigh and Moustaki (1999), Moustaki and O'Muircheartaigh (2000), and Moustaki and Knott (2000). Usually, the covariates X provide the information needed to model the missing data indicators D . However, the missing data indicators D may also depend on latent variables which are not directly observed. In the next section, an example is given to get a flavor of the approach.

Example: Modeling Item Nonresponse in Educational Assessments

Educational assessments are often based on a test with dichotomously scored items. Data from such tests are analyzed using a so-called IRT model (see, e.g., Lord, 1980). An example is the one-parameter logistic model

(1PLM; Rasch, 1960). In the 1PLM, the probability of a correct response is given by

$$p(y_{ik} = 1 | \zeta_i, \beta_k) = \frac{\exp(\zeta_i - \beta_k)}{1 + \exp(\zeta_i - \beta_k)}$$

where ζ_i is the so-called latent ability parameter for student i , and β_k is the so-called difficulty parameter of item k . The likelihood function is obtained using eqn [1]. In most practical situations, the slightly more complex two- and three-parameter logistic models are used (Lord, 1980); however, the 1PLM suffices for the example presented here. In IRT, it is mostly assumed that the ability parameters ζ_i are random effects and that the item parameters β_k are fixed effects. For technical reasons (which are not important here), the likelihood function is integrated over the random effects and the fixed effect parameters are estimated by marginal ML (MML; see Bock and Aitkin, 1981).

In most applications of educational assessment, it can be assumed that the missing data are ignorable. As argued, this also holds for the two-stage testing design discussed above. However, there are situations where ignorability may be violated. For instance, when students skip items they find too difficult and this skipping depends on a latent variable that is highly correlated with the latent ability variable. For these situations, Holman and Glas (2005) formulate a model where the missingness indicators also follow the 1PLM, that is,

$$p(d_{ik} = 1 | \eta_i, \delta_k) = \frac{\exp(\eta_i - \delta_k)}{1 + \exp(\eta_i - \delta_k)}.$$

Note that η_i is a student parameter that is positively related to endorsing the item and δ_k is an item parameter that is negatively related to endorsing the item. Holman and Glas (2005) introduce the assumption that ζ_i and η_i have a bivariate normal distribution. The mean and variance parameters of this distribution are set equal to zero and one, respectively, to identify the location and scale of the latent variables. The correlation between ζ_i and η_i , say ρ , is a free parameter to be estimated. The complete model is given by

$$p(Y_{obs}, D | \theta, \phi) = p(Y_{obs} | D, \zeta, \beta) p(D | \eta, \delta) p(\zeta, \eta | \rho)$$

If $\rho \neq 0$, ignorability is violated because the priors of the parameters of the distribution of the observations $\theta = (\zeta, \beta)$ and those of the missing data indicators $\phi = (\eta, \delta)$ are dependent. The assumption of ignorability only holds if $\rho = 0$.

To show the impact of violation of ignorability on the estimates of the item parameters, a small part of a larger study by Holman and Glas (2005) is shown. Using the model, data were generated for 1000 simulated students, responding to ten items. To keep the presentation simple, an example will be given where all item parameters are

equal to zero, that is, $\beta_k = \delta_k = 0$ for all k . The latent variables ζ_i and η_i were drawn from a bivariate normal distribution with mean and variance equal to one and zero, respectively, and a correlation ρ . Using these parameters, missing data indicators d_{ik} and item responses y_{ik} were generated according to the model. The correlation ρ was varied from 0.0 to 0.9 in steps of 0.1. For every value of ρ , 100 replications were made, that is, 100 data matrices with 1000 simulees and ten items were generated and analyzed. MML estimates were computed for two models: a model labeled MAR where only the item parameters β were estimated and a model labeled NONMAR where the item parameters β , δ , and ρ were estimated. The results are shown in **Table 1**.

The column labeled MAR gives the mean absolute error (MAE) of the estimates of the item parameters under the MAR model averaged over all items and all replications. The true values of the item parameters are all zero; therefore, it can be seen that the MAE in the estimates of the item parameters under the MAR model increases with the magnitude of the violation of ignorability. That is, if there is no violation ($\rho = 0.0$), then the MAE is 0.091, and the severest violation ($\rho = 0.9$) produces an MAE of 0.273. The columns under the label NONMAR give the MAE of the estimates of parameters under the NONMAR model. Note that the MAE of the estimates of the item parameters does not increase with the magnitude of the violation of ignorability. The MAE of the estimate of the correlation between the two latent dimensions does increase. However, a breakdown of this MAE into bias and random estimation error showed that this increase was due to the higher standard errors for lower correlations. Therefore, the estimates of the correlations were not biased. The conclusion is that an analysis under an unjustified assumption of ignorability leads to biased estimates, but the bias is removed by modeling the process that caused the missing data.

Table 1 Mean absolute error of MML parameter estimates under MAR and NONMAR models using 1000 simulees, 10 items, and 100 replications for each value of ρ

ρ	Model				
	MAR		NONMAR		
	β	β	δ	ρ	
0.0	0.091	0.092	0.060	0.055	
0.1	0.075	0.075	0.066	0.048	
0.2	0.086	0.084	0.057	0.053	
0.3	0.121	0.087	0.065	0.058	
0.4	0.131	0.095	0.062	0.054	
0.5	0.152	0.084	0.057	0.037	
0.6	0.147	0.089	0.068	0.033	
0.7	0.186	0.089	0.068	0.034	
0.8	0.200	0.090	0.058	0.026	
0.9	0.273	0.088	0.054	0.010	

An application of an analogous approach is found in the work by Glas and Pimentel (2008). The application concerns an analysis of data from a subscale of the *Nederlandse Intelligentietest voor Onderwijsniveau* (NIO), which is an intelligence test for students in primary education in the Netherlands (van Dijk and Tellegen, 2004). The IRT model for the observed data was the 2PLM. The model for the missing data indicators was an IRT model by Tutz (1997). This model is a generalization of the 1PLM. MML estimates of the parameters were obtained both for the MAR model and the NONMAR model. The correlation between ζ and η was estimated as 0.429, which gives an indication that the missing data process cannot be ignored. The differences between the estimates obtained using the MAR and NONMAR models are plotted in **Figure 1**. The first panel shows how the number of students responding to an item decreases from 3145 to 508. The second panel gives the differences in the estimates of the difficulty parameters β under the two models. Note that the difference increases toward the end of the test. Therefore, the bias in the parameter estimates

Figure 1 (a) Numbers of students reaching items and (b) the differences of item difficulty estimates between MAR and NONMAR models.

increases as the sample of students responding to an item becomes more and more select. Thus, here also, the conclusion is that the violation of ignorability resulted in biased parameter estimates.

Model Selection

S J Haberman, Educational Testing Service, Princeton, NJ, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Bayesian inference – A method of statistical inference in which conclusions about populations are made by combining sample data with prior knowledge concerning population measures.

Continuous variable – A variable such as height or weight which can assume any value in an interval of positive length.

Discrete variable – A variable which assumes a finite or countable number of values.

Hypothesis test – A method of statistical inference in which a statistic based on observed data is used to assess consistency of observed data with a hypothesis concerning a population measure.

Item-response model – A model employed to describe the probability that an examinee in an assessment has any specific pattern of responses.

Likelihood-ratio test – A test of a hypothesis which compares the compatibility of data with model parameters consistent with a specified hypothesis to the compatibility of data with model parameters consistent with an alternative hypothesis.

Linear model – A model which uses a linear function of one or more explanatory variables to predict a response variable.

Multiple-choice test – An assessment in which examinees select an answer to each test item from a list of alternatives.

Pearson chi-square test – A hypothesis test used with discrete data to assess the compatibility of a probability model with the data.

Penalty function – A function used to measure prediction error.

Model selection is a common activity in statistical analysis of data. Two somewhat different approaches can be found. In the first approach, a model is regarded as appropriate for the data if, according to hypothesis tests, the model is consistent with the data. Among models consistent with the data, comparisons may be made in terms of parsimony or in terms of relative consistency with the data. In the second approach, models are compared in terms of their ability to predict data. It is not regarded as likely that any model under study is consistent with data. Instead, prediction measures are estimated and compared for the models under consideration. The second approach becomes

increasingly important as sample sizes become large, for inconsistency of models with data becomes an increasingly serious issue in such cases (Gilula and Haberman, 2001). In this article, the sections on likelihood-ratio tests, Pearson chi-square tests, and Bayesian inference emphasize the approach based on hypothesis tests. The sections on penalty criteria and linear models emphasize prediction measures.

To illustrate some common issues in model selection, consider selection of a model for the responses on a multiple-choice test. For illustrative purposes, data will be used from a writing test with $q = 45$ items numbered from 1 to q . Data are available for $n = 8686$ examinees i numbered from 1 to n (Haberman, 2005, 2007b). For each examinee i and item j , the observation $X_{ij} = 1$ if the response is correct and 0 if the response is not correct. In psychometrics, several common item-response models are often applied to data of this kind. In each item-response model, it is assumed that there are independently distributed unobserved random variables θ_i which represent the abilities of the examinees i , $1 \leq i \leq n$. As is typically the case in applications of these models, the unobserved variables are assumed to have a standard normal distribution. It is assumed that, given the θ_i , the X_{ij} are conditionally independent and, for a particular examinee i and item j , the conditional probability that $X_{ij} = 1$ (the response is correct) only depends on the ability variable θ_i associated with the examinee. The conditional probability that $X_{ij} = 1$ given $\theta_i = \omega$ is $P_j(\omega)$ for some unknown function P_j defined for all real numbers. The models considered are models for P_j . In the one-parameter logistic (1PL) model, it is assumed that, for some unknown constants a and γ_j

$$P_j(\omega) = \frac{\exp(a\omega - \gamma_j)}{1 + \exp(a\omega - \gamma_j)}$$

In the special case of $a = 0$, one obtains the independence model (Ind) that the X_{ij} , $1 \leq j \leq q$, are mutually independent and that the probability is positive that $X_{ij} = k$ for k equal 0 or 1. In the two-parameter logistic (2PL) model, it is assumed that, for some unknown slope parameter a_j and intercept parameter γ_j

$$P_j(\omega) = \frac{\exp(a_j\omega - \gamma_j)}{1 + \exp(a_j\omega - \gamma_j)}$$

In the three-parameter logistic (3PL) model, it is assumed that, for some unknown slope parameter a_j , some

unknown intercept parameter γ_j and some unknown lower asymptote c_j $0 \leq c_j < 1$,

$$P_j(\omega) = c_j + (1 - c_j) \frac{\exp(a_j\omega - \gamma_j)}{1 + \exp(a_j\omega - \gamma_j)}$$

The 1PL model is a special case of the 2PL model in which the slope parameters a_j have a common value a , and the 2PL model is a special case of the 3PL model in which the lower asymptotes c_j are all 0. The basic question to consider is how to decide which of these models is most appropriate for the data under study. One approach considered will be based on tests of hypotheses. The other approach will be based on the ability of the models to describe the joint distribution of the item responses X_{ij} $1 \leq j \leq q$, associated with an examinee i (Hambleton *et al.*, 1991).

Likelihood-Ratio Tests

The models under study may be compared by the use of likelihood-ratio tests (Wilks, 1938). For any vector \mathbf{x} of possible responses x_j equal 0 or 1, $1 \leq j \leq q$, let $p(\mathbf{x})$ be the joint probability that, for some examinee i , the response X_{ij} to item j is x_j for $1 \leq j \leq q$. The distribution of the vector \mathbf{X}_i of responses X_{ij} $1 \leq j \leq q$, is determined by the q -dimensional array \mathbf{p} of probabilities $p(\mathbf{x})$, $0 \leq x_j \leq 1$, $1 \leq j \leq q$. To each model corresponds a set S of possible arrays of probabilities, so that the model holds if, and only if, \mathbf{p} is in S . For example, the independence model holds if, and only if, \mathbf{p} is in the set $S(0)$ of arrays such that

$$p(\mathbf{x}) = \prod_{j=1}^q \frac{\exp(x_j \gamma_j)}{1 + \exp(\gamma_j)}$$

for some real γ_j $1 \leq j \leq q$. In like fashion, if θ is a random variable with a standard normal distribution, then the 1PL model holds if, and only if, \mathbf{p} is in the set $S(1)$ of arrays such that $p(\mathbf{x})$ is the expected value of

$$\prod_{j=1}^q \frac{\exp[x_j(a\theta - \gamma_j)]}{1 + \exp(a\theta - \gamma_j)}$$

for some real a and real γ_j $1 \leq j \leq q$. In like manner, a set $S(2)$ may be defined to correspond to the 2PL model, and a set $S(3)$ may be defined to correspond to the 3PL model. The saturated, or unrestricted, model holds for \mathbf{p} in the set T of arrays with $p(\mathbf{x})$ positive and the sum of all $p(\mathbf{x})$ equal to 1.

The log likelihood function

$$\ell(\mathbf{p}) = \sum_{i=1}^n \log p(\mathbf{X}_i)$$

is the logarithm of the probability that the observed vectors \mathbf{X}_i are obtained for $1 \leq i \leq n$. For a model that \mathbf{p} is in S , likelihood-ratio tests are based on the maximum

$\ell(S)$ of the log likelihood for probability arrays in S . For a subset S' of S , the model that \mathbf{p} is in S' may be compared to a model that \mathbf{p} is in S by the likelihood-ratio chi-square statistic

$$L^2(S, S') = 2[\ell(S) - \ell(S')]$$

In typical cases, if \mathbf{p} is in S' , then $L^2(S, S')$ has an approximate chi-square distribution with $k(S) - k(S')$ degrees of freedom, where $k(S)$ is the dimension of the space S and $k(S')$ is the dimension of S' . Thus, the approximate significance level is the probability $P(S, S')$ that a chi-square variable with $k(S) - k(S')$ degrees of freedom exceeds the observed value of $L^2(S, S')$. The approximation improves as the sample size n increases. If the model that \mathbf{p} is in S' does not hold, then the typical result is that $P(S, S')$ converges to 0 with probability 1 as the sample size increases.

In the comparison of the 1PL to the 2PL model for the data under study, the set $S(1)$ corresponding to the 1PL model has dimension $q + 1$, for there are q unrestricted parameters γ_j and one unrestricted parameter a . The set $S(2)$ corresponding to the 2PL model has dimension $2q$, for there are q unrestricted parameters γ_j and q unrestricted parameters a_j . The resulting chi-square approximation has $2q - (q + 1) = q - 1 = 44$ degrees of freedom in the case under study. The statistic $L^2(S(2), S(1)) = 3772$, so that the approximate significance level is extremely close to 0. In other words, either the 1PL model does not hold, or a very rare event has taken place. In like fashion, one may readily compare the independence model to the 1PL model, for $S(0)$ has q unrestricted parameters. Thus, $k(S(1)) - k(S(0))$ is $q + 1 - q = 1$, and $L^2(S(1), S(0)) = 22109$, so that the approximate significance level is extremely small.

One might expect that the comparison of the 2PL model to the 3PL model would proceed just as the comparison of the 1PL model to the 2PL model and the comparison of the independence model to the 1PL model, but this expectation is not met. The likelihood-ratio chi-square statistic $L^2(S(3), S(2)) = 646$ is readily found, but the chi-square approximation does not hold due to the constraints on the lower asymptote parameters c_j . Under the 2PL model, c_j is at the boundary value 0 of its range. This constraint typically results in a large-sample distribution that is less likely to exceed any given value $x > 0$ than is the chi-square distribution with $k(S(3)) - k(S(2)) = q$ degrees of freedom. Because q is 45, it remains evident that the 2PL model does not hold.

In principle, one could compare the model that \mathbf{p} is in $S(m)$, m equal 0, 1, 2, or 3 to the saturated model that \mathbf{p} is in T , but the chi-square approximation again fails. The problem arises because T has dimension $2^q - 1 = 3.51 \times 10^{13}$, a very large number relative to the sample size n . For use of $L^2(T, S(m))$, it is commonly recommended that the expected number $np(\mathbf{x})$ of \mathbf{X}_i equal \mathbf{x} be at least 1 for all possible values \mathbf{x} of \mathbf{X}_i and that $np(\mathbf{x})$ should be at least 5

for at least 80% of the possible \mathbf{x} (Cochran, 1954). Use of T can be illustrated if one confines attention to the first four responses X_{ij} $1 \leq j \leq 4$, for in this case, the conditions for the chi-square approximation hold. For the independence model, $L^2(T, S(0))$ is 410.7, and there are $2^4 - 1 - 4 = 11$ degrees of freedom, so that $P(T, S(0))$ is very small. Similarly, $L^2(T, S(1)) = 289.1$, and there are $2^4 - 4 = 12$ degrees of freedom for the chi-square approximation, so that $P(T, S(1))$ is very close to 0. Thus the independence and 1PL model for the first four responses do not appear to be compatible with the data. In the case of the 2PL model, $L^2(T, S(2))$ is 20.6, and $2^4 - 2(4) - 1 = 7$ degrees of freedom are associated with the chi-square approximation, so that $P(T, S(2))$ is about 0.0044. This probability is sufficiently low that evidence exists that the 2PL model does not hold for the first four responses; however, the evidence is much less substantial than in the case of the independence or 1PL model.

A convenient feature of likelihood-ratio chi-square statistics is the existence of simple decompositions. For example,

$$L^2(S, S') = L^2(T, S') - L^2(T, S)$$

For instance, in the example with the four initial responses, $L^2(S(2), S(1))$, the comparison statistic for the 1PL model against the 2PL model, is $L^2(T, S(1)) - L^2(T, S(2)) = 268.5$, and the chi-square approximation has $12 - 7 = 5$ degrees of freedom. In this particular example, this comparison provides very strong evidence against the 1PL model. This result is consistent with the previous finding for the test statistic $L^2(T, S(1))$ comparing the 1PL model to the saturated model.

Likelihood-ratio tests may be employed for comparisons of more than two models. Let S be a family of subsets of T . For each S in this family, one may consider the model that \mathbf{p} is in S . In the simplest case, consider a base model that \mathbf{p} is in U , where U includes every set S in the family S but U itself is not a member of the family of models to be compared. One may then consider comparison of the model that \mathbf{p} is in S to the model that \mathbf{p} is in U by means of the likelihood-ratio chi-square $L^2(U, S)$ and the corresponding approximate significance level $P(U, S)$. For instance, in the four-response case, let U be T , so that the base model is the saturated model, and let S contain $S(m)$ for m from 0 to 2, so that the independence model, the 1PL model, and the 2PL model are compared to the saturated model. Preference is given to 2PL model that \mathbf{p} is in $S(2)$, for $P(U, S(2))$ is larger than $P(U, S(0))$ or $P(U, S(1))$. A related criterion based on ratios of likelihood-ratio chi-square statistics to approximate expected values is the F statistic $F(U, S) = L^2(U, S)/[k(U) - k(S)]$. The smallest $F(U, S)$ is sought for S in S (Goodman, 1971; Haberman, 1974). For the four-response example, the best result is again for the 2PL model, for $F(T, S(2)) = 2.9$ is much smaller than $F(T, S(0))$ or $F(T, S(1))$.

Pearson Chi-Square Tests

Although less convenient in the application under study, it should be noted that the Pearson chi-square statistic can be used instead of the likelihood-ratio chi-square (Pearson, 1900; Fisher, 1924). This option typically uses maximum-likelihood estimates to compare the model that \mathbf{p} is in S' to the model that \mathbf{p} is in S under the condition that S' is included in S . The array $\hat{\mathbf{p}}_S$ of probabilities $\hat{p}_S(\mathbf{x})$ is the maximum-likelihood estimate of \mathbf{p} under the model that \mathbf{p} is in S if $\hat{\mathbf{p}}$ is in S and $\ell(\hat{\mathbf{p}}_S) = \ell(S)$. In the case of the unrestricted model that \mathbf{p} is in T , $\hat{\mathbf{p}}_T = \bar{\mathbf{p}}$, the array of fractions $\bar{p}(\mathbf{x})$ of examinees i with $\mathbf{X}_i = \mathbf{x}$. One has

$$X^2(S, S') = n \sum_{\mathbf{x}} [\hat{p}_S(\mathbf{x}) - \hat{p}_{S'}(\mathbf{x})]^2 / \hat{p}_{S'}(\mathbf{x})$$

(Haberman, 1977). The large-sample approximations for $X^2(S, S')$ and $L^2(S, S')$ are the same. The most common applications use $S = T$. For instance, in the four-question case, to test the independence model that \mathbf{p} is in $S(0)$, one can use $X^2(T, S(0)) = 409.0$ in place of $L^2(T, S(0)) = 410.7$ without appreciable effect.

Whether Pearson or likelihood-ratio chi-square statistics are employed, a typical problem in model selection is that no model of any interest is compatible with the data if the sample size n is large (Gilula and Haberman, 2001).

Continuous Data

Although the working example involves discrete variables, it should be emphasized that likelihood-ratio chi-square statistics are also commonly applied to continuous data to examine compatibility of models with data. The basic difference is that in the log likelihood, probabilities are replaced by probability densities. The likelihood function continues to be maximized for each model compared, chi-square approximations remain, and computations of degrees of freedom are unchanged.

Penalty Criteria

An alternative approach to model selection compares models in terms of predictive power rather than in terms of fitting data. This approach often employs information theory (Gilula and Haberman, 2001). One may illustrate arguments by using the results of the 45-item multiple-choice test previously employed to illustrate use of tests of significance. In the approach under study, probability prediction is employed. A probability array \mathbf{u} is used to predict the observation \mathbf{X}_i . The value of the array as a predictor is judged by use of the penalty $-\log u(\mathbf{X}_i)$ (Savage, 1971). This penalty only depends on the probability assigned to the observed value of the responses \mathbf{X}_i .

and the penalty is non-negative. The penalty is 0 if, and only if, the observed responses \mathbf{X}_i have assigned probability 1. The expected penalty is then

$$G(\mathbf{u}) = E(-\log u(X_i))$$

The expected penalty is never less than the entropy

$$H = G(\mathbf{p}) = E(-\log p_{X_i})$$

and $G(\mathbf{u}) = H(\mathbf{p})$ if, and only if, the probability prediction \mathbf{u} is the actual probability array \mathbf{p} .

The penalty criterion may be employed to assess the quality of a model that \mathbf{p} is in S . If the probability array \mathbf{p} is known, then model error may be evaluated by use of the minimum $G(S)$ of G for probability arrays in S . The difference $G(S) - H$ is a measure of model error. The measure is non-negative, and, if \mathbf{p} is in S , then $G(S) = H$ and the error $G(S) - H = 0$. To compare models that \mathbf{p} is in S for S in a family \mathcal{S} of subsets of T , the smallest $G(S)$ is sought for S in \mathcal{S} .

In practice, \mathbf{p} is not known, so that $G(S)$ and H must be estimated. Estimation of $G(S)$ is generally feasible given the log-likelihood maximum $\ell(S)$, for $G(S)$ may be estimated by $\hat{G}(S) = -\ell(S)/n$. In principle, H has estimate $\hat{H} = -\ell(T)/n$; however, this estimate is not satisfactory unless conditions hold for the chi-square approximation to the likelihood-ratio chi-square statistic $L^2(T, S)$. For S' contained in S , $\hat{G}(S') - \hat{G}(S)$ is $L^2(S, S')/(2n)$, and $\hat{G}(S') - \hat{G}(S)$ can be employed to measure the improvement in the model that \mathbf{p} is in S relative to the model that \mathbf{p} is in S' . For example, for the case of the data with 45 items, $\hat{G}(S(0))$ is 28.110, $\hat{G}(S(1))$ is 26.838, $\hat{G}(S(2))$ is 26.621, and $\hat{G}(S(3))$ is 26.583. Despite the very strong evidence that the 1PL model does not hold, the measured difference $\hat{G}(S(1)) - \hat{G}(S(2))$ is relatively small, only 0.217. In contrast, $\hat{G}(S(0)) - \hat{G}(S(1))$ is 1.273. The relative reduction in estimated expected penalty

$$\frac{\hat{G}(S(1)) - \hat{G}(S(2))}{\hat{G}(S(1))} = 0.0081$$

for the 2PL model relative to the 1PL model is quite small compared to the relative reduction

$$\frac{\hat{G}(S(0)) - \hat{G}(S(1))}{\hat{G}(S(0))} = 0.0453$$

for the 1PL model relative to the independence model. The contrast between the 2PL and the 3PL model demonstrates even less difference, for $\hat{G}(S(2)) - \hat{G}(S(3))$ is only 0.037, and

$$\frac{\hat{G}(S(2)) - \hat{G}(S(3))}{\hat{G}(S(2))} = 0.0014$$

is very modest in size.

The estimate $\hat{G}(S)$ is biased. In addition, if one wishes to consider prediction of a new observation \mathbf{X}_{n+1} with the same distribution as the \mathbf{X}_i , $1 \leq i \leq n$, and one wishes to

base the prediction on estimates computed from \mathbf{X}_i , $1 \leq i \leq n$, then further correction is needed. One measure for prediction of \mathbf{X}_{n+1} is the Akaike estimate

$$G_a(S) = \hat{G}(S) + k(S)/n$$

This correction is only satisfactory if the model that \mathbf{p} is in S is valid. An alternative approach (Gilula and Haberman, 2001) uses a criterion $G_g(S)$ similar to the Akaike criterion that does not assume that the model holds. It is also possible to consider $G_c(S) = \hat{G}(S) + bk(S)$ for a positive real constant b , so that a penalty for model complexity is imposed without regard to sample size.

The Bayesian analysis in the next section leads to the Schwarz criterion

$$G_s(S) = \hat{G}(S) + (2n)^{-1}k(S) \log n$$

In large samples, $\hat{G}(S)$ and the criteria of Akaike, Schwarz, and Gilula and Haberman are very similar. For instance, for the 2PL model for 45 items, $G_a(S(2))$ and $G_g(S(2))$ are 26.631 to five significant figures, while $G_s(S(2))$ is 26.668. The data suggest that the 3PL model is slightly preferable to the 2PL model unless $G_c(S(2))$ is compared to $G_c(S(3))$ with the coefficient b at least 0.00083. The advantage of the 2PL model relative to the 1PL model is larger under all criteria, and $G_c(S(1))$ is greater than $G_c(S(2))$ unless b is at least 0.00482.

In the case of continuous data, similar arguments can often be used to those which have been employed for discrete data (Gilula and Haberman, 2000); however, as in the case of likelihood-ratio tests, arguments are based on density and functions rather than on probabilities.

Bayesian Inference

Bayesian inference can be employed to select models (Kass and Raftery, 1995). For example, consider the data with 45 items and S equal to the set of $S(m)$ for m from 0 to 3. Assume that the 3PL model does hold and that comparison is between the independence model, the 1PL model, the 2PL model, and the 3PL model. One may divide the set $S(3)$ corresponding to the 3PL model into four disjoint sets $U(0)$, $U(1)$, $U(2)$, and $U(3)$. Here $U(0)$ is $S(0)$ and, for k equal 1, 2, or 3, $U(k)$ consists of members of $S(k)$ that are not in $S(k-1)$. Thus, $U(0)$ corresponds to the independence model, while $U(1)$ corresponds to case in which the 1PL model holds but the independence model holds. Let the prior probability that \mathbf{p} is in $U(k)$ be $\pi_k > 0$ for $0 \leq k \leq 3$, and let Π_k be the prior distribution of \mathbf{p} given that \mathbf{p} is in $U(k)$. In typical cases, each Π_k is associated with some positive probability densities on the set of model parameters which correspond to \mathbf{p} in $U(k)$. For \mathbf{p} in $U(0)$, a positive density is assigned to the q -dimensional vector with coordinates γ_j for $1 \leq j \leq q$. Similarly, for \mathbf{p} in

$U(1)$, a positive density is assigned to the $(q+1)$ -dimensional vector with coordinates γ_j , $1 \leq j \leq q$, and $a, a \neq 0$. Similar requirements are imposed for \mathbf{p} in $U(2)$ or for \mathbf{p} in $U(3)$. Given these prior distributions, Bayes's theorem can be employed to compute the conditional probability p_k that \mathbf{p} is in $U(k)$ given the observed \mathbf{X}_i , $1 \leq i \leq n$. This conditional probability depends on the log-likelihood function $\ell(\mathbf{u})$ for \mathbf{u} in $S(3)$. In this case, large values of p_k suggest use of the model that \mathbf{p} is in $S(k)$.

Two practical obstacles exist. The value p_k depends on prior distributions that may be difficult to specify in a realistic manner. Computation of p_k is very difficult, although numerical quadrature, simulation methods, and approaches based on Laplace transforms can be considered. A very crude approximation can often be based on the Schwarz criterion $G_s(S(k))$ for $0 \leq k \leq 3$. Under relatively general conditions

$$\frac{n[G_s(S(g)) - G_s(S(k))] - \log(p_k/p_g)}{\log(p_k/p_g)}$$

converges in probability to 0 as the sample size n increases. This result may be used to show that p_k converges in probability to 1 if \mathbf{p} is in $U(k)$. In the example under study, the result favors the 3PL model to the extent that $G_s(S(k))$ is smallest for $k = 3$.

The Bayesian approach described here does not have any obvious basis if \mathbf{p} is not contained in $S(3)$. This restriction is severe if one takes the position that nontrivial models are rarely valid.

Linear Models

Model selection need not be based on complete probability models. A common case involves linear models. For example, consider a sample of n essays, for each of which both holistic scores generated by two human raters and computer-generated essay features are available (Haberman, 2007a). For essay i , let Y_i be the average of the two holistic scores, and let X_{ij} be the numerical value of essay feature j , $1 \leq j \leq k$. For example, X_{i1} might be the square root of the number of characters in essay i . For each essay i , the computer-generated features X_{ij} , $1 \leq j \leq k$, are to be employed to predict the average holistic score Y_i . A simple approach considers a linear predictor

$$\tilde{Y}_i = \alpha + \sum_{j=1}^k \beta_j X_{ij}$$

for some real constants α and β_j , $1 \leq j \leq k$. The prediction error is $Y_i - \tilde{Y}_i$. If \mathbf{X}_i is the vector with coordinates X_{ij} , $1 \leq j \leq k$, then one may consider the case of pairs (Y_i, \mathbf{X}_i) that are independently and identically distributed. Let Y_i have finite and positive variance $V(Y)$, and let \mathbf{X}_i have finite and positive-definite covariance matrix $\text{Cov}(\mathbf{X})$.

The expected mean-square error is then the expected value $E([Y_i - \tilde{Y}_i]^2)$. If the mean $E(Y)$ of the Y_i , the mean $E(\mathbf{X})$ of the \mathbf{X}_i , the variance $V(Y)$ of the Y_i , the covariance matrix $\text{Cov}(\mathbf{X})$, and the covariance vector $\text{Cov}(\mathbf{X}, Y)$ with elements $\text{Cov}(X_{ij}, Y_i)$, $1 \leq j \leq k$, are all known, then the expected mean-squared error $E([Y_i - \tilde{Y}_i]^2)$ is minimized if

$$\tilde{Y}_i = E(Y) + \beta'[\mathbf{X}_i - E(\mathbf{X})]$$

where β , the vector of β_j , $1 \leq j \leq k$, is $[\text{Cov}(\mathbf{X})]^{-1} \text{Cov}(\mathbf{X}, Y)$. The resulting mean square error, denoted by $V(Y|\mathbf{X})$, is the residual variance of Y_i given \mathbf{X}_i . In principle, $V(Y|\mathbf{X})$ can form the basis for evaluation of the value of \mathbf{X}_i in prediction of Y_i .

In practice, means, variances, and covariances must be estimated. Let

$$\bar{X} = n^{-1} \sum_{i=1}^n X_i$$

denote the sample mean of the X_i , and let

$$\bar{Y} = n^{-1} \sum_{i=1}^n Y_i$$

denote the sample mean of the Y_i . The least-squares estimates a of α and \mathbf{b} of β satisfy the equations

$$\begin{aligned} \hat{Y}_i &= a + \sum_{j=1}^k b_j X_{ij} \\ a &= \bar{Y} - \mathbf{b}'\bar{\mathbf{X}} \end{aligned}$$

and

$$\sum_{i=1}^n (Y_i - \hat{Y}_i) X_i = 0$$

Here \mathbf{b} has coordinates b_j , $1 \leq j \leq k$, and $\mathbf{0}$ is the k -dimensional vector with all coordinates 0. As the sample size n becomes large,

$$\hat{V}(Y|\mathbf{X}) = n^{-1} \sum_{i=1}^n (Y_i - \hat{Y}_i)^2$$

approaches $V(Y|\mathbf{X})$ with probability 1, so that $\hat{V}(Y|\mathbf{X})$ may be employed to evaluate the effectiveness of \mathbf{X}_i in linear prediction of Y_i . Thus, $\hat{V}(Y|\mathbf{X})$ can provide a basis for selection of different predictors \mathbf{X} of Y .

Corrections are commonly made to treat biases due to the finite sample size (Draper and Smith, 1998). In standard regression analysis, the assumption is added that, given \mathbf{X}_i , the conditional mean of Y_i is \tilde{Y}_i and the conditional variance of Y_i is $V(Y|\mathbf{X})$. In this case, if \mathbf{X} is continuous and $n > k + 1$, then $V(Y|\mathbf{X})$ has the unbiased estimate

$$\bar{V}(Y|\mathbf{X}) = \frac{n}{n-k-1} \hat{V}(Y|\mathbf{X})$$

These assumptions do not hold exactly in the essay example, for the X_{ij} are discrete variables and the traditional

assumptions of regression are not likely to hold exactly given that holistic scores have a limited range, which in the data to be examined is from 1 to 6.

An alternative approach with fewer assumptions uses PRESS residuals (Draper and Smith, 1981; 325–327). The idea is to predict a new average holistic score Y_{n+1} by using the observed (Y_i, \mathbf{X}_i) , $1 \leq i \leq n$, and the new computer-generated features $X_{(n+1)j}$, $1 \leq j \leq n$. Under traditional regression analysis, the mean squared error from prediction of Y_{n+1} by $\hat{Y}_{n+1} = a + \mathbf{b}'\mathbf{X}_i$ is $V(Y|\mathbf{X})^{\frac{n+k+1}{n}}$, and this mean square error has unbiased estimate $\bar{V}(Y|\mathbf{X})^{\frac{n+k+1}{n}}$. Without traditional assumptions, one may employ PRESS residuals. For each essay i , least-squares estimates a_i for α and b_{ji} , $1 \leq j \leq k$, for β_j are obtained by minimizing the sum of the $(Y_m - \hat{Y}_{mi})^2$ for $1 \leq m \leq n$, $m \neq i$, where

$$\hat{Y}_{mi} = a_i + \sum_{j=1}^k b_{ji} X_{mj}$$

This approach estimates this mean squared error for prediction of Y_{n+1} by

$$\hat{V}_p(Y|\mathbf{X}) = n^{-1} \sum_{i=1}^n (Y_i - \hat{Y}_{ii})^2$$

where

$$\hat{Y}_{ii} = a_i + \sum_{j=1}^k b_{ji} X_{ij}$$

This approach might appear tedious; however,

$$Y_i - \hat{Y}_{ii} = (Y_i - \hat{Y}_i) / (1 - \bar{H}_{ii})$$

for

$$\hat{H}_{ii} = n^{-1} + (\mathbf{X}_i - \bar{\mathbf{X}})' \left[\sum_{m=1}^n (\mathbf{X}_m - \bar{\mathbf{X}})(\mathbf{X}_m - \bar{\mathbf{X}})' \right]^{-1} (\mathbf{X}_i - \bar{\mathbf{X}})$$

(Draper and Smith, 1998; 207–208) It is clearly desirable to have $\hat{V}_p(Y|\mathbf{X})$ smaller.

For one case with 4895 essays and $k = 6$ predictors, one has $\hat{V}_p(Y|\mathbf{X}) = 0.238$. An alternative predictor was considered with $k = 56$ predictors. This case had $\hat{V}_p(Y|\mathbf{X}) = 0.235$, so that a very modest gain was achieved with a much larger set of predictors. A further very modest gain was achieved with 206 predictors, for $\hat{V}_p(Y|\mathbf{X})$ went to 0.232. Whether the modest gain is really worth the cost in terms of predictors needed is a matter of judgment.

Concluding Remarks

Model selection issues are much more varied than can be indicated in a brief survey. The emphasis in this article has

been on simple random sampling. Modifications for more complex sampling are readily accomplished. Although the emphasis here has been on independent observations, model selection is also an issue in the analysis of time series in which observations are dependent. Except for the discussion of linear models, ability of independent variables to predict dependent variables has not been explored. Use of models which involve such prediction arises for polytomous dependent variables as well as for linear models (Gilula and Haberman, 2001). The emphasis in this article has involved situations in which the sample sizes are relatively large and the number of models to consider is relatively small. When sample sizes are not very large and when the number of models is large, then issues of selection bias must be considered. In these cases, a model is much more likely to appear to be the most appropriate due to random variation rather than due to actual superiority of the model. This issue is frequently encountered in regression analysis (Draper and Smith, 1998). In general, model selection depends on the nature of the data, the sample size, and the intended application of the results. The approach must be adapted to the problem at hand.

Glossary

Bayesian – An approach to statistical inference in which parameters are treated as random variables, allowing Bayes rule $p(y|x) = p(x|y)p(y)/p(x)$ to be used to perform inference. It is named after Reverend Thomas Bayes.

Bias – An estimator is biased if its expectation differs from the true value; the bias of the estimator is the difference between its expectation and the truth.

Consistency – A sequence of estimators is consistent if it converges, as the number of samples approaches infinity, to the true value. Such a sequence is asymptotically unbiased.

Expectation – The expectation (or expected value) of a random variable is, in a sense, the mean value that an infinite ensemble of independent replicates would have. In some sense, it quantifies the value which one would expect a realization to have, but there is no requirement that the expectation is a value which the random variable can take: for example, a Bernoulli random variable with parameter p can take values 0 and 1, but has expectation p .

iid (independent and identically distributed) – A collection of random variables is said to be iid if those variables are independent and share a common distribution. That is, each may be considered to be a single realization of the same probability distribution.

Independent – Random variables are independent if knowledge of one provides no information about the others. Formally, one can require that the conditional distribution of any one of the random variables given the other is the marginal distribution of that random variable, that is, $p_{Y|X}(y|x) = p_Y(y)$ if X and Y are independent.

Markov Chain – A temporally ordered collection of random variables with the property that conditional upon the present, the future is independent of the past.

Background and History

Monte Carlo methods may be thought of as a collection of computational techniques for the (usually approximate)

solution of mathematical problems, which make fundamental use of random samples. Two classes of statistical problems are most commonly addressed within this framework: integration and optimization. This article concentrates on the former: it is the (approximate) calculation of integrals using collections of random samples that people usually think of when they refer to the Monte Carlo Method. Monte Carlo methodology is also widely used in the simulation of physical, chemical and biological systems.

In the field of education, Monte Carlo methods are most interesting as a computational device for performing statistical inference. Many interesting models have extremely complex structures and cannot easily be dealt with using traditional techniques. Within the Bayesian paradigm, all information upon which inference can be based is encoded within the posterior probability distribution. Using Monte Carlo methods, we are able to characterize these distributions, and calculate expectations under them: the primary inferential technique.

A Simple Example

Monte Carlo methods invert the usual problem of statistics: rather than estimating random quantities in a deterministic manner, random quantities are employed to provide estimates of deterministic quantities. For example, one simple Monte Carlo experiment considers rain which falls uniformly at random (i.e., the location of any raindrop may be interpreted as a realization of a uniformly distributed random variable) over some square region of space, and a circle inscribed within that square. Without reference to any formal probability theory, it is intuitive that the probability of a uniform raindrop falling in any region within the square must be proportional to the area of that region and independent of its location. Consequently, the probability, p , that a raindrop lies within the inscribed circle may be expressed in terms of their areas. If the square has sides of length $2r$, the circle must be of radius r and

$$p = \frac{\pi r^2}{(2r)^2} = \frac{\pi}{4}$$

In itself, this may not seem particularly interesting. However, having expressed π as a function of this probability, its estimators can be used to approximate π . Proceeding analytically is not possible: obtaining the probability requires knowledge of π . Intuitively, it is possible to estimate this probability by counting the proportion of

raindrops which lie within the circle: if n raindrops are observed and m of those lie within the circle, then one may estimate p , using $\hat{p} = m/n$. **Figure 1** shows a computer simulation in which 500 raindrops were distributed uniformly over a square – in this case, $\hat{p} = 383/500$ and, defining $\hat{\pi}$ through the relationship between p and π , $\hat{\pi} = 383/125 = 3.06$. A poor estimate of π , considering the computational effort used, but it is an estimate nonetheless. In fact m is a realization of a binomial (n, p) random variable.

History

While there is some debate about the nature of the first Monte Carlo computations ever carried out (with some authors arguing that they date back as far as the times of ancient Babylon), it is generally agreed that the first modern Monte Carlo experiments were carried out in the later decades of the nineteenth century and, similar to the above example, were concerned with the estimation of π .

Consider dropping a needle of length l uniformly onto an array of parallel lines separated from one another by a distance, $d > l$. **Figure 2** illustrates this. Originally, the question was: What is the probability that the needle intersects a line? This question is relatively easy to answer. Assume that the array is large enough that edge effects are negligible, and assume that the x and y coordinates of the needles center are uniform over the array and the orientation of the needle is uniformly distributed over the interval $[0, \pi)$.

Figure 1 Estimating π : 383 of the 500 samples lie within the circle.

As **Figure 2** illustrates, the needle intersecting a line is equivalent to a rectangle of width $l \sin \theta$ intersecting that line. This happens, for given θ , with probability

$$\mathbb{P}(\text{intersection}|\theta) = \frac{l \sin \theta}{d}$$

The angle θ is uniform on $[0, \pi)$; hence,

$$\begin{aligned} \mathbb{P}(\text{intersection}) &= \int_0^\pi \mathbb{P}(\text{intersection}|\theta) \frac{1}{\pi} d\theta \\ &= \frac{l}{\pi d} \int_0^\pi \sin \theta d\theta = \frac{2l}{\pi d} \end{aligned}$$

Consequently, if n needles are dropped, then the average number which would intersect a line if the experiment were carried out many times is $2nl/d\pi$.

In a Monte Carlo setting, this means that π may be estimated using:

$$\hat{\pi} = \frac{2nl}{Md}$$

where M is the number of needles crossing a line when n are dropped. In 1901, Mario Lazzarini reported carrying out this experiment using a 2.5-cm-long needle and lines separated by $d = 3$ cm. Of his 3408 needles, 1808 crossed a line, suggesting

$$\pi \approx \frac{2 \times 3408 \times 2.5}{1808 \times 3} = \frac{355}{113}$$

which, remarkably, corresponds to the best rational approximation to π with denominator below 16 000, leading to suggestions that this was an early example of fabricated data.

Although these early examples of Monte Carlo techniques were, in some sense, successful, the cost of carrying out the experiments rendered them largely impractical and of only specialist interest. This began to change in Los Alamos in the 1940s, when physicists working on particle transport problems began solving them using something

Figure 2 Buffon's needles: thicker needles intersect the grid lines.

which they termed the Monte Carlo method. The precise origin of the name varies from one account to another, but there is general agreement that it stems from its relationship with the games of chance played in the casinos of Monte Carlo. The revolutionary step introduced at this time was the use of random number generators (and, latterly, digital computers producing pseudorandom numbers) in place of physical experiments to perform the calculation.* The physics community has continued to contribute to the development of Monte Carlo methodology to the present day.

Perhaps the final revolution in Monte Carlo methodology occurred during the 1980s, during which the increasing use of Bayesian methods and the associated need to evaluate complex high-dimensional integrals led to interest in and development of the methods by the statistics community. This was the point at which the use of Monte Carlo methods to approximate general integral expressions became widespread. The increased interest also drove – and continues to drive – the development of methodology and theory among researchers outside of the traditional application domains of Monte Carlo integration.

Elementary Methods

This section introduces the basic elements of the Monte Carlo method and places them upon a theoretically justified footing.

The Monte Carlo Method

The expected value $\mathbb{E}(X)$ of a random variable, X , which has a probability density function (pdf), f , may be thought of as the average value it would take if the experiment that produced X were carried out infinitely many times. It may be written in the form of an integral:

$$\mathbb{E}(X) = \int xf(x)dx$$

where integration is carried out over the full range of values which X may assume. In the case of discrete random variables with a probability mass function f , the integral is replaced by a summation, but nothing fundamental changes. In this article, random variables will be assumed to be continuous for notational simplicity, but no significant difficulties arise when applying these techniques in a discrete domain.

Underlying the Monte Carlo method is the (strong) law of large numbers which formalizes this concept. If X_1, X_2, \dots

are a collection of independent and identically distributed (iid) random variables with common distribution f , and $\varphi : E \rightarrow \mathbb{R}$ is a function with finite expectation, then

$$\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{i=1}^n \varphi(X_i) = \mathbb{E}(\varphi(X))$$

where convergence holds with probability 1.

A refinement of this result is provided by the central limit theorem. If we also have that $\mathbb{E}(\varphi(X)^2) < \infty$, then

$$\lim_{n \rightarrow \infty} \sqrt{n} \left(\frac{1}{n} \sum_{i=1}^n \varphi(X_i) - \mathbb{E}(\varphi(X)) \right) \Rightarrow \mathcal{N}(0, \sigma^2)$$

Where ‘ \Rightarrow ’ denotes convergence in distribution. That is, \sqrt{n} times the sample mean converges in distribution to a normal random variable with variance σ^2 .

The most elementary Monte Carlo method may be justified directly using these two theorems. If we wish to estimate the expectation, $\mathbb{E}(\varphi(X))$, where X is a random variable with density function f , from which we can obtain samples, then we may use the empirical mean of φ obtained from a large sample to estimate the expectation of interest. Given a collection of iid random variables X_1, \dots, X_m which have common distribution f , the simple Monte Carlo estimator of $\mathbb{E}(\varphi(X))$ is

$$\frac{1}{n} \sum_{i=1}^n \varphi(X_i)$$

This may be connected with the rainfall experiment presented earlier by considering a function which takes a value of 1 within the circle and 0 outside and calculating its expectation under the distribution of the co-ordinates which is uniform over the square. To see this explicitly, writing this function as

$$\mathbb{I}_{\text{circle}}(x, y) = \begin{cases} 1 & \text{if } x^2 + y^2 \leq r \\ 0 & \text{otherwise} \end{cases}$$

makes it clear that the area of the circle of interest is equal to the integral of this function over any region which includes the circle, such as the square in which it is inscribed. Consequently, our representation for π may be written in the form

$$\begin{aligned} \pi/4 = p &= \frac{\int_{-r}^r \int_{-r}^r \mathbb{I}_{\text{circle}}(x, y) dx dy}{(2r)^2} \\ &= \int_{-r}^r \int_{-r}^r \frac{1}{(2r)^2} \mathbb{I}_{\text{circle}}(x, y) dx dy \end{aligned}$$

Approximating the final line in this expression through the simple Monte Carlo method would give exactly the same estimator as that described above. The term $1/(2r)^2$ corresponds to the density of the uniform distribution over the square $[-r, r] \times [-r, r]$ and, therefore, the integral may be approximated by sampling pairs of points (X, Y) from this distribution and calculating the mean value of the function $\mathbb{I}_{\text{circle}}$ at the sampled points.

* Pseudorandom numbers are generated deterministically but share certain statistical properties with random numbers. A detailed discussion is beyond the scope of this article.

In order to employ simple Monte Carlo, it is necessary to be able to sample from the distribution of interest. This requirement is not necessarily easily satisfied: Monte Carlo methods are generally used to deal with complicated distributions which do not admit tractable analytic solutions and it can be very difficult to obtain samples from such distributions. Two generally-applicable methods for obtaining samples from known distributions are introduced below, and this is followed by a method for estimating expectations under a distribution using samples from a different distribution. That is, the following two methods which are techniques for sampling from a distribution of interest: the samples obtained by these methods can be used in the simple Monte Carlo method described above. The third technique is a Monte Carlo method in its own right: it provides estimates of expectations directly without using samples from the distribution of interest.

Inversion Sampling

The distribution function, F , associated with a pdf, f , is defined as $F(x) = \int_{-\infty}^x f(y)dy$. If X is distributed according to f , then $F(x) = \mathbb{P}(X \leq x)$. The generalized inverse of a distribution function, F , may be defined as:

$$F^-(p) = \inf\{x : F(x) \geq p\}$$

That is, it is the smallest value of x such that $F(x)$ is at least p . Note that this differs from the inverse only if F is discontinuous (a situation which arises whenever there is a finite probability of the associated random variable taking a particular value).

Inversion sampling transforms a random variable, U , with a uniform distribution on the interval $[0, 1]$ (i.e., a random variable with density 1 over $[0, 1]$ and 0 elsewhere), by setting $X = F^-(U)$. If F^- is the generalized inverse of the distribution function of interest, then X has the distribution of interest:

$$\begin{aligned}\mathbb{P}(X \leq x) &= \mathbb{P}(F^-(U) \leq x) \\ &= \mathbb{P}(U \leq F(x)) \\ &= F(x)\end{aligned}$$

Figure 3 illustrates the method. The hollow circles on the vertical axis correspond to three realizations of U and the filled circles on the horizontal axis are the corresponding realizations of X . This method can be used to sample realizations of any one-dimensional real-valued random variable, provided that the inverse of the distribution function is known.

The Fundamental Theorem and Rejection Sampling

A more general approach is motivated by the fact that sampling a collection of random variables according to a given density is equivalent to sampling uniformly in the

Figure 3 Inversion sampling. Filled circles illustrate samples from the illustrated distribution function.

area under the density graph and discarding the additional dimension. In the case of a real-valued random variable, X , for example, saying that it has density f means that the probability that X lies between x and $x + dx$ is $f(x)dx$ for infinitesimal dx . If we divide the region between $f(x)$ and the x -axis into infinitesimal squares of uniform area and subsequently select one uniformly at random, then it will lead to a sample for X with the same distribution (the number of boxes in the strip of interest is, of course, proportional to $f(x)$) (see **Figure 4** for an illustration). More formally, sampling uniformly from the region $\{(x, u) : 0 \leq u < f(x)\}$ and retaining only x is equivalent to sampling x according to $f(x)$. This is sometimes known as the fundamental theorem of sampling.

Of course, one cannot usually sample uniformly from this region by any direct means – if anything, it is more difficult than sampling from the distribution of interest. Rejection sampling provides samples uniformly under the graph of the density of interest by sampling from a larger area and rejecting those samples which fall outside the region of interest. Formally, given a density, g , from which it is possible to obtain samples and some known constant, $M \geq \sup_x \frac{f(x)}{g(x)}$, one can consider the following algorithm to obtain a sample from f :

- (1) Sample X from g .
- (2) Sample U from $\mathcal{U}(0, M)$.
- (3) If $U > f(X)/g(X)$ reject X and go to 1.
- (4) Accept X as a sample from f .

Figure 5 illustrates the principle: the filled circles indicate accepted samples (which are distributed uniformly beneath the bimodal density) and the hollow circles were rejected (samples were generated uniformly in the area under the rescaled unimodal density).

Figure 4 The fundamental theorem of sampling: loosely, sampling from a strip in the left panel with a probability proportional to its height produces a sample with the same distribution over X as would be obtained by choosing a box in the right panel uniformly at random.

Figure 5 Rejection sampling. Filled circles indicate accepted samples.

Notice that, on average, one sample in M is accepted:

$$\begin{aligned}\mathbb{P}(X \text{ Accepted}) &= \mathbb{P}(U \leq f(X)/g(X)) \\ &= \frac{1}{M} \mathbb{E}[f(X)/g(X)] = \frac{1}{M}\end{aligned}$$

Consequently, for this to be an efficient strategy, it must be possible to sample from a distribution for which a small value of the constant M can be found.

Verifying that the distribution of the accepted samples is, indeed, f , is a simple matter of considering the

probability that a sample lies in an infinitesimal neighborhood, dx , of a point x given that it is accepted:

$$\begin{aligned}\mathbb{P}\left(X \in dx \mid U \leq \frac{f(X)}{g(X)}\right) &= \mathbb{P}\left(X \in dx, U \leq \frac{f(X)}{g(X)}\right) / \mathbb{P}\left(U \leq \frac{f(X)}{g(X)}\right) \\ &= \mathbb{P}(X \in dx) \mathbb{P}\left(U \leq \frac{f(X)}{g(X)} \mid X \in dx\right) / \frac{1}{M} \\ &= g(x)dx \times \frac{1}{M} \frac{f(x)}{g(x)} \times M = f(x)dx\end{aligned}$$

The envelope or squeeze method is a technique for reducing the computational cost of samples obtained by rejection sampling. If cheap-to-evaluate upper and lower bounds for the ratio $f(x)/g(x)$ exist, then it is possible to automatically accept those samples for which U is less than the lower bound and reject those for which it exceeds the upper bound. This means that it is only necessary to evaluate the ratio itself (an operation which may be relatively slow) if the sampled value of U lies in the interval between these two bounds. This can produce substantial computational savings if the bounds are well chosen.

Importance Sampling

Inversion and rejection sampling make it possible to obtain samples from a number of distributions. Unfortunately, many distributions of interest to statisticians are too complicated to allow the efficient generation of samples by these methods. Importance sampling is one

strategy which makes it possible to deal with distributions from which one cannot sample efficiently.

Importance sampling makes use of a distribution other than that of interest, but is used specifically for calculating expectations as it attaches a weight to each sample based on its significance to the integral of interest. If f is the density of interest, we wish to calculate the expectation of φ under that distribution:

$$\begin{aligned} E(\varphi(X)) &= \int \varphi(x)f(x)dx \\ &= \int \varphi(x)\frac{f(x)}{g(x)}g(x)dx \end{aligned}$$

provided that $f(x)/g(x) < \infty$. An importance sampling estimate of the expectation of φ with respect to f is obtained by calculating the simple Monte Carlo estimate of $\varphi f/g$ with samples, X_1, \dots, X_m from g :

$$\int_E \varphi(x)f(x)dx \approx \frac{1}{n} \sum_{i=1}^n \frac{f(X_i)}{g(X_i)} \varphi(X_i)$$

This is illustrated in **Figure 6**.

Importance sampling has a number of advantages over other methods. It does not require that one can simulate from the distribution of interest (in common with rejection sampling) and it does not require that one can obtain a constant M which bounds the ratio $f(x)/g(x)$ (unlike rejection sampling). Even if it is possible to sample directly from f , it can be possible to obtain lower variance estimates if a good choice of proposal distribution, g , is made. Indeed, if φ is a positive function, then choosing $g(x) \propto f(x)\varphi(x)$ will lead to zero variance estimates:

a single sample will yield the exact answer. Unfortunately, this optimal proposal distribution can rarely be used in practice. However, approximations to it, from which it is possible to sample, can often be employed. A widely accepted guideline for the selection of a proposal distribution is that it should lead to bounded importance weights. This is not always necessary to obtain estimates of finite variance, but it is sufficient. In particular, this guideline requires that the tails of the proposal distribution should be at least as heavy as those of the target (and its support must be at least as large as that of the target – that is a general requirement of importance sampling).

As presented above, it is necessary to know $f(x)/g(x)$ pointwise. A simple modification to the algorithm (which leads to an estimator which is biased for finite samples, but consistent, and which typically reduces the variance) allows for situations in which $f(x)/g(x)$ is only known up to a normalizing constant. If $w(x) = Cf(x)/g(x)$, then $\int w(x)\varphi(x)g(x)dx = C\mathbb{E}(\varphi)$ and therefore, if we let $\mathbf{1}$ denote the unit function (the function which maps everything to 1), then we know that:

$$\frac{\int w(x)\varphi(x)g(x)dx}{\int w(x)\mathbf{1}(x)g(x)dx} = \frac{C\mathbb{E}(\varphi)}{C\mathbb{E}(\mathbf{1})} = \mathbb{E}(\varphi)$$

By approximating both the numerator and denominator using a collection of samples from g , an estimator for $\mathbb{E}(\varphi)$ is given by

$$\frac{\sum_{i=1}^n w(X_i)\varphi(X_i)}{\sum_{i=1}^n w(X_i)}$$

This is often referred to as the self-normalized importance sampling estimator.

Figure 6 Importance sampling: ten samples and their weights (vertical lines) from a proposal distribution (dotted line) weighted according to the weight function (solid line) appropriate for the target distribution (dashed line).

Variance Reduction Techniques

One criterion which can be used to assess the performance of a Monte Carlo technique is the variance of the estimators which it produces. Reducing this variance is one of the principal aims of the designer of a Monte Carlo simulation. The intuition behind three widely applicable techniques for doing this is presented in this section.

Rao-Blackwellization

If the random variable of interest X may be decomposed as $X = (Y, Z)$ and it is possible to calculate the expectation of the function of interest, φ , given a particular value of Z , then the estimator obtained by performing this integration (the expectation of $\varphi(X)$ conditional on a value of Z is, of course, the integral of that function with respect to the conditional distribution of X given Z) is never worse than that defined on the joint space (in that it has small variance and, by the tower property of expectation, the

same mean $\mathbb{E}[\mathbb{E}(\varphi|Z)] = \mathbb{E}[\varphi]$. This can be seen by considering the straightforward variance decomposition:

$$\begin{aligned}\text{Var}(\varphi(Y, Z)) &= \text{Var}(\mathbb{E}[\varphi|Z]) + \mathbb{E}[\text{Var}(\varphi|Z)] \\ &\Rightarrow \text{Var}(\mathbb{E}[\varphi|Z]) \leq \text{Var}(\varphi(Y, Z))\end{aligned}$$

That is, if it is possible to integrate out some subset of the random variables, then it is always preferable to do so. This is sometimes referred to as Rao-Blackwellization because of its connection to the Rao-Blackwell theorem.

Control Variates

If one knows the expectation of some function ψ under the distribution of interest, then one may use its Monte Carlo estimate (using the same sample as that used to estimate the integral of the function of interest, φ) to create an estimator of 0. When suitably weighted, this estimator will, under certain conditions, have a negative correlation with the estimator of ψ and may be used to reduce its variance. Calculation of the weight required to obtain a variance reduction may not be straightforward.

Antithetic Variables

If one can obtain two estimators of the integral of interest based upon a random sample (in the case of a symmetric distribution, e.g., it is possible to use the reflection of the sample set to provide a second estimator) and which are negatively correlated then the variance of the average of these estimators will be less than that of either one and will certainly outperform the poorer of the two estimators. This is the principle behind the technique of antithetic variables.

More Advanced Approaches

Inevitably, more advanced techniques than those described above are required to deal with complex problems. This section provides a necessarily brief overview of three more sophisticated techniques.

Markov Chain Monte Carlo

Markov chain Monte Carlo (MCMC) is a technique which is widely used to deal with complex distributions for which the methods described above prove inadequate. They employ suitable sequences of dependent random variables to approximate integrals of interest rather than attempting to obtain independent samples. It is possible to obtain results showing the consistency of such estimates, and that they obey a central limit theorem under certain regularity conditions.

Quasi-Monte Carlo

Quasi-Monte Carlo (QMC) is not really a Monte Carlo technique at all. In QMC, integrals are approximated using deterministic (rather than random) sequences of variables which are chosen to have a property termed low discrepancy. This approach can be interpreted as making a virtue of the inability of computers to provide truly random numbers by selecting points according to an analytic criterion, rather than attempting to mimic randomness. Such methods can exhibit theoretically faster convergence than Monte Carlo approaches, especially when used for the integration of smooth functions in low-dimensional spaces. Numerical simulations have verified this for simple problems in spaces of small dimension. In practice, it has proved difficult to obtain the promised performance improvements in more interesting problems and some care is required when implementing these methods.

Sequential Monte Carlo

Sequential Monte Carlo (SMC) is a term used to refer to algorithms which obtain samples from a sequence of distributions by using an iterated importance sampling strategy together with some refinements. Historically, these algorithms have been widely used for online estimation in time-series problems; more recently, it has been shown that they provide an effective way to obtain samples from general distributions.

Glossary

(Dis)similarity – The term similarity is used to indicate the degree of likeness between two objects, while dissimilarity indicates the degree of unlikeness. For example, red and pink are more similar (less dissimilar) to each other than red and green. (Red and green are more dissimilar (less similar) than red and pink.) In the similarity data, a larger value indicates more similar objects, while in the dissimilarity data, a larger value indicates more dissimilar objects.

Distance Models – The models used to represent (dis)similarity data in MDS. Although there are other distance models, the Euclidean distance model is the most popular one used in MDS.

Multidimensional scaling (MDS) – A set of data analysis techniques for analysis of similarity or dissimilarity data. It is used to represent (dis)similarity data between objects by a variety of distance models.

Unfolding analysis – One way of representing individual differences in preference judgments. In unfolding analysis, subjects' ideal objects and actual objects are represented as points in a joint multidimensional space in such a way that the distances between them are as inversely related to the observed preferences as possible.

The notion of similarity plays a fundamental role in human cognition (Takane *et al.*, 2009). It serves as an organizing principle by which people categorize, generalize, and classify objects. Multidimensional scaling (MDS) is a set of data analysis techniques for representing (dis)similarity data (similarity or dissimilarity data) by spatial distance models (Takane, 2007). In this article, we explicate the purposes, the mechanism, and the variety of uses of MDS.

This article consists of the following sections: (1) "Introduction," through an example, to illustrate the basic roles and the uses of MDS, (2) "Distance models, fitting criteria, and the data collection methods," (3) "Scale levels and data transformations," (4) "Dimensionality selection," (5) "Individual differences MDS," (6) "Unfolding analysis," and (7) A summary and software for MDS.

Introduction

Some objects are more similar (or dissimilar) to each other than others. For example, red and pink are more similar than red and green. MDS represents the similarity or dissimilarity data among the objects by mapping the points (representing the objects) into a multidimensional space in such a way that the distances between them best accord with the observed (dis)similarity data between the objects. In the above example, the points representing red and pink are located closer in the space than the points representing red and green. By virtue of MDS, we can visually inspect the (dis)similarity data among the objects and investigate the principle underlying the organization of the (dis)similarity data.

To further illustrate the role of MDS, let us take a look at the data in **Table 1**. This table shows dissimilarity data among eight different sports. The names of two sports were presented each time to the subjects, who were asked to indicate the degree of dissimilarity between them on a 11-point rating scale. Entries in the table indicate average dissimilarities between the sports across ten subjects. The eight sports are: (1) baseball, (2) basketball, (3) rugby, (4) soccer, (5) softball, (6) table tennis, (7) tennis, and (8) volleyball. MDS was applied to the table, and the derived object configuration is presented in **Figure 1**.

By inspection, it can readily be seen that MDS indeed located the points corresponding to similar objects close together, while locating those corresponding to dissimilar objects far apart. **Figure 1** shows that the eight sports are roughly classified into four groups, the first consisting of rugby and soccer, the second consisting of volleyball and basketball, the third consisting of baseball and softball, and the fourth consisting of tennis and table tennis. This is consistent with our intuition that the sports within the groups have much in common. The four groups of sports may further be combined in various ways to form larger clusters. For example, baseball, softball, rugby, and soccer might be grouped into one, and the remaining sports (basketball, volleyball, tennis, and table tennis) into the other. Since the first group occupies the upper right portions of the configuration, and the second group lower left portions, we may interpret the direction from upper right to lower left contrasting sports that use a big outdoor field with those that require only a medium- to small-size court. We may also group baseball, softball, tennis, and table tennis into one group, and the remaining sports (rugby,

Table 1 Mean dissimilarity ratings among eight sports

The eight sports are: 1. baseball, 2. basketball, 3. rugby, 4. soccer, 5. softball, 6. table tennis, 7. tennis, and 8. volleyball.

Figure 1 The two-dimensional object configuration of the eight sports from average dissimilarity ratings in **Table 1** (a PROXSCAL solution obtained under the assumption of interval-scaled dissimilarity data and with 100 random initial starts; normalized raw stress = 0.020).

soccer, volleyball, and basketball) into the other. The former use a relatively small ball, while the latter use a big ball. We may call the direction from upper left to lower right the ball size dimension. MDS, simply stated, is a sort of gadget that draws a map similar to the one presented in **Figure 1** based on a set of distance-like quantities (similarity or dissimilarity data) similar to the ones given in **Table 1**. The map facilitates our intuitive understanding of the relationships among the objects represented in the map.

Distance Models, Fitting Criteria, and the Data Collection Methods

As noted above, MDS represents interobject (dis)similarities by interpoint distances. While there are a variety of distance models that may be used in MDS, the one most

Figure 2 Calculating the Euclidean distance between two points in the two-dimensional space.

frequently used is the Euclidean distance model. Let x_{ir} denote the coordinate of point i (object i) on dimension r . Then, the Euclidean distance between points i and j is calculated by

$$d_{ij} = \left\{ \sum_{r=1}^R (x_{ir} - x_{jr})^2 \right\}^{1/2} \quad [1]$$

where R indicates the dimensionality of the space. Once x_{ir} 's are given, we can locate the points in the space using a Cartesian coordinate system, and we can calculate the distance between them using the above formula. Suppose that $R = 2$, and the coordinates of point 1 on the two dimensions are 3 and 2 ($x_{11} = 3$ and $x_{12} = 2$), and the coordinates of point 2 are 1 and 4 ($x_{21} = 1$ and $x_{22} = 4$). Then, these two points can be located as indicated in **Figure 2**. The Euclidean distance between them can be calculated by $d_{12} = \{(3 - 1)^2 + (2 - 4)^2\}^{1/2} = \sqrt{8} \approx 2.828$. MDS locates the points (i.e., finds their coordinates), representing the objects in such a way that the set of distances calculated from the coordinates best agree with the observed (dis)similarities between the objects.

One important feature of the Euclidean distance is that it is invariant over the choice of origin and orientation of coordinate axes. In MDS, we typically place the origin at the centroid of the object configuration, and rotate the configuration in such a way that the coordinate axes represent substantively meaningful attributes. (Note, however, that some distance models used in MDS, e.g., the weighted Euclidean model, do not allow rotation of axes without changing the interpoint distances. See the section entitled "Individual differences MDS.")

Observed data typically contain a sizable amount of measurement errors, and an exact representation of the data is usually impossible. Rather, we look for the best approximation of the observed (dis)similarity data. To make this notion more rigorous, we need to introduce an index that measure's the goodness (or badness) of agreement between the observed data and the distance model. This index also serves as a criterion to be optimized in MDS. That is, an MDS procedure systematically looks for the object configuration that maximizes the goodness (or minimizes the badness) of fit of the distance model to the observed (dis)similarity data.

Two broad classes of goodness of fit criteria have been used in MDS. One is the least squares (LS) criterion (Kruskal, 1964a, 1964b), and the other is the maximum likelihood (ML) criterion (Ramsay, 1977, 1982). Although the latter has some appeal for its statistical inference capabilities, the former has been far more predominantly used in MDS for its simplicity and flexibility. Let o_{ij} denote the observed dissimilarity between objects i and j (temporarily assumed to have been measured on a ratio scale; see the next section for scale levels of measurement), and let d_{ij} denote the corresponding distance between points i and j in the Euclidean space. Then, the LS criterion is defined by:

$$\phi(\{x_{ir}\}) = \sum_{i < j} (o_{ij} - d_{ij})^2 \quad [2]$$

where $\{x_{ir}\}$ is a collection of object coordinates. (The LS criterion of the above form is often called raw stress in the MDS literature.) This is a badness of fit criterion, meaning that a larger value indicates a larger discrepancy between the distance model and the observed dissimilarity data. The LS MDS attempts to find the set of object coordinates $\{x_{ir}\}$ so as to minimize the discrepancy between the observed o_{ij} and the predicted d_{ij} .

A minimization of the LS criterion generally involves a very complicated process because the distance model is not a simple linear function of its parameters (object coordinates). The equations to be satisfied at the minimum of ϕ usually cannot be solved in closed form, and some kind of iterative methods have to be used to solve them. In the iterative methods, successive approximations to the final solution are obtained by gradually improving the goodness of fit of the solution, starting from an initial guess, until a sufficiently close approximation is found. See the work by Borg and Groenen (2005) for more details of the algorithms used in MDS.

One potential danger of this kind of iterative optimization procedures is known as the problem of convergence to nonglobal minima. The LS criterion used in MDS may have multiple local minima, and iterative optimization procedures may be caught up by one of them that is not the true minimum of the criteria we wish to find. Fortunately, computers nowadays are so powerful that it is not

at all unrealistic to obtain multiple solutions starting from many different initial estimates. Multiple solutions may be compared in terms of their goodness of fit, and the best solution can be chosen, which is more likely to be the globally optimal solution we want.

A variety of (dis)similarity measures may be used as input data to MDS, including (dis)similarity ratings, sorting data, confusion data, frequency of co-occurrences, response latency (reaction time data), frequency of social interactions, profile similarity, and so on. In the (dis)similarity rating methods, objects are presented in pairs to the subjects, who are asked to rate the degree of (dis)similarity between them on a rating scale. (The data from the example presented earlier on dissimilarity among eight sports were collected by this method.) In the sorting method, subjects are given a set of objects and are asked to group them into several groups in terms of their similarity. The number of times two objects are put into same groups is counted over a group of subjects and used as a similarity measure between the objects. See the work by Takane *et al.* (2009) for more systematic descriptions of the data collection methods used in MDS.

Scale Levels and Data Transformations

Scale levels refer to approximate relationships that may be assumed to hold between observed dis(similarity) data and distances. The distinction between different scale levels is important because certain MDS procedures only apply to dis(similarity) data measured on certain scale levels.

There are four scale levels considered in MDS: ratio, interval, log interval, and ordinal. Let o_{ij} denote the observed dissimilarity between objects i and j , and let d_{ij} denote the corresponding distance. In the ratio scale level, it is assumed that $o_{ij} \approx d_{ij}$, where \approx means approximately equal. In this case, d_{ij} can be directly fitted to o_{ij} so as to minimize criterion [2]. No data transformation is necessary. However, it is rare to find the ratio-scaled measurement in social science research.

In the interval-scaled measurement, it is assumed that $o_{ij} \approx ad_{ij} + b$, where a is $+1$ if the data are dissimilarity data, or -1 if they are similarity data (o_{ij} can be either similarity or dissimilarity data), and b is an additive constant. In the case of interval-scaled data, the fitting criterion is generalized into

$$\phi(\{x_{ir}\}, b) = \sum_{i < j} (\pm o_{ij} - d_{ij} - b)^2 \quad [3]$$

and both the object configuration and an optimal value of b have to be estimated that jointly minimize the criterion.

In a log-interval scale, it is assumed that $o_{ij} \approx bd_{ij}^a$, that is, the observed (dis)similarity data are related to underlying distances by a power transformation. When the log is

taken on both sides of the above relationship, we obtain $\ln o_{ij} \approx a \ln d_{ij} + \ln b$, which is a linear relationship between $\log o_{ij}$ and $\log d_{ij}$ similar to the interval scale level, hence the name log-interval scale. Not many MDS procedures recognize this scale level as such, and the (dis)similarity data at this scale level are often analyzed as mere ordinal-scaled data.

In the ordinal scale level, o_{ij} and d_{ij} are assumed to be only monotonically related. That is, $o_{ij} > o_{i'j'}$ implies $d_{ij} \geq d_{i'j'}$ if the data are dissimilarity data, whereas $o_{ij} > o_{i'j'}$ implies $d_{ij} \leq d_{i'j'}$ if the data are similarity data. MDS procedures that are capable of handling ordinal (dis)similarity data are called nonmetric MDS (Shepard, 1962; Kruskal, 1964a, 1964b) and enjoy widest applications. The fitting criterion in this case is modified into:

$$\phi(\{x_{ir}\}, m) = \sum_{i < j} (m(o_{ij}) - d_{ij})^2 \quad [4]$$

where m denotes a monotonic (or an inversely monotonic) transformation. MDS procedures in this case have to find the best monotonic transformation of the ordinal data as well as the object configuration $\{x_{ir}\}$ that jointly minimize the above criterion.

We usually do not know *a priori* exact scale levels that the observed (dis)similarity data satisfy. As a practical strategy, we may start with a weaker assumption, but as soon as we find, as a result of the analysis, that a stronger measurement assumption can be justified, we switch to the stronger assumption. In this way, we can get more reliable results while avoiding unaffordable scale level assumptions.

Dimensionality Selection

One important decision that has to be made in MDS concerns the dimensionality of the solution space. The dimensionality refers to the number of coordinates needed to locate a point in the spatial representation of objects. There are several considerations that should be taken into account in determining the number of dimensions. The derived object configuration has to fit to the data at hand reasonably well, but should not fit too well. A better fit to the data at hand can generally be achieved by merely increasing the dimensionality of the solution space, and too good a fit may compromise the predictability of the model for future observations. One practical strategy for determining the adequate number of dimensions is to analyze the data under varied dimensionalities, say from 1 to 4, plot the fit value against the dimensionality (this is called a scree plot), and identify the point where the improvement in fit flattens out. Such a point is called an elbow in the scree plot.

Another important consideration in determining the dimensionality of the solution space is the interpretability of derived dimensions. Uninterpretable dimensions are

useless and should not be retained (even if they are necessary to account for the observed (dis)similarity data sufficiently well).

In the example of sports data, the raw stress values were 0.186 for the unidimensional solution, 0.020 for the two-dimensional solution, 0.003 for the three-dimensional solution, and 0.001 for the four-dimensional solution. The two-dimensional solution was easily interpretable, whereas the third-dimensional one was not. Thus, the two-dimensional solution was selected as the best one.

Individual Differences MDS

So far, we have assumed that there is only one set of (dis)similarity data. In many applications of MDS, however, (dis)similarity data are collected from a group of subjects. If no systematic individual differences exist, a single common Euclidean distance model may be fitted to all of them simultaneously, or a single Euclidean distance model is fitted to average (dis)similarity data, as has been done in the example presented earlier. In many situations, however, the assumption of no systematic individual differences is unrealistic. In such a case, each (dis)similarity matrix may be analyzed separately, yielding as many object configurations as there are (dis)similarity matrices. A natural question is how they are related. In most cases, there are both common and unique aspects in (dis)similarity judgments obtained from different individuals. If so, we need a methodology that captures both aspects.

The individual differences (ID) MDS model captures both commonality and individual differences in (dis)similarity judgments (Carroll and Chang, 1970). More specifically, it postulates a common object configuration that applies to all individuals; however, dimensions in the common configuration are differentially weighted by different individuals to give rise to differences in (dis)similarity judgments. The idea of differential weighting of dimensions can be captured by the weighted Euclidean distance model:

$$d_{ijk} = \left\{ \sum_{r=1}^R w_{kr} (x_{ir} - x_{jr})^2 \right\}^{1/2} \quad [5]$$

where d_{ijk} is the distance between points (objects) i and j for individual k , x_{ir} is, as before, the coordinate of object i on dimension r in the common object configuration, and w_{kr} is the weight attached to dimension r by subject k . To eliminate the size indeterminacy between the object configuration and the individual difference weights, the former is typically constrained to satisfy $\sum_{i=1}^n x_{ir}^2 / n = 1$ for $r = 1, \dots, R$. In contrast to the simple Euclidean distance model [1], the orientation of the coordinate axes is uniquely determined in the weighted Euclidean distance model. ID MDS estimates both the object coordinates $\{x_{ir}\}$ and the individual differences weights $\{w_{kr}\}$ in such a way

that d_{ijk} calculated from them best agree with the observed dissimilarity between objects i and j by subject k .

As an example of ID MDS, let us look at the data in **Table 2** obtained from ten subjects. This is the original data from which the data in **Table 1** were calculated by averaging them over the ten subjects. Individual differences MDS was applied to the ten dissimilarity matrices. **Figure 3** displays the derived two-dimensional common object configuration. In the figure, the sports that use a big ball are located toward the right, and those that use a small ball toward the left, so that the horizontal axis can be interpreted as representing the ball size dimension. The vertical axis, on the other hand, places the sports that use a big field at the top, and those that use a small court at the bottom, thus contrasting between the two. (As has been alluded to above, coordinate axes are unrotatable in the weighted Euclidean model, so that we don't have to search for meaningful directions in the space. We simply try to interpret the directions of the coordinate axes.) **Figure 4** depicts the individual differences weights attached to the two dimensions by different subjects. In the figure, two extreme subjects are identified by subject numbers. Subject 6 puts the most emphasis on dimension 1 among all the subjects, whereas subject 10 does so on dimension 2, although, in this particular example, the weights are relatively homogeneous, indicating that there are not many differences in the way the two dimensions are evaluated by the different subjects. In some cases, the weights may show interesting patterns of differences that may be related to subjects' background information such as gender, age, level of education, etc., but, unfortunately, such information is unavailable in the present case (see the work by Takane (2007) for more examples of interesting applications of the ID MDS).

Figure 3 The two-dimensional common object configuration of the eight sports obtained by individual differences MDS of dissimilarity data in Table 2 (a PROXSCAL solution under the assumption of ordinal dissimilarity data and matrix conditional; normalized stress = 0.052).

Figure 4 The plot of individual differences weights attached to the two dimensions by the ten subjects for the data in Table 2.

Unfolding Analysis

Individual differences are far more prevalent in preference judgments. Preference data are often analyzed by a variant of MDS called unfolding analysis (Coombs, 1964).

In unfolding analysis, each subject is assumed to have an ideal object represented as the subject's ideal point in the same space as actual objects are represented. The distances between the ideal point and the object points are assumed to be inversely related to the subject's preferences on the objects. Let x_{ir} denote the coordinate of object i on dimension r , and y_{jr} the coordinate of subject j 's ideal point on dimension r . The Euclidean distance between object point i and ideal point j is calculated by

$$d_{ij} = \left\{ \sum_{r=1}^R (x_{ir} - y_{jr})^2 \right\}^{1/2} \quad [6]$$

The coordinates of the ideal and object points are determined in such a way that the preference values of the objects for a particular subject are a decreasing function of the distances between them. This implies that the closer an object point is to his ideal, the more preferred the object is by that subject. The preference relations are thus regarded as representing similarity relations between the subjects' ideal objects and actual objects. In unfolding analysis, we are given an N by n data matrix obtained from N subjects making preference judgments on n objects. By subjecting the data matrix to unfolding analysis, we obtain two coordinate matrices, one for object points and the other for subjects' ideal points.

As an example of unfolding analysis, let us look at Table 3. Thirty-one subjects rank-ordered six different colors from the least preferred to the most preferred. The data are thus similarity data with greater numbers indicating more preferred colors and greater similarities between subjects' ideal color and actual colors. Ties were allowed, and were given the average of ranks they would have received if they were not exactly tied. The six colors used in the study are: orange (o), blue (b), grass color (g1), green (g2), red (r), and purple (p). PREFSCAL (Busing, Groenen, and Heiser, 2005) was used to analyze the data.

Figure 5 depicts the joint MDS configuration of the subject's ideal points and the six colors. The first five subjects in the data set are identified by the integers. By inspection, colors most preferred by these subjects are located close to these subjects' ideal points. For example, subject 1 prefers blue and grass color, while subject 2 red and purple. Subject 5's ideal point is somewhat outlying (from the rest), indicating that another form of preference model called the vector preference model may be more appropriate for the subject (Busing *et al.*, 2005). The analysis was run under the interval scale level assumption rather than the ordinal scale assumption, which was probably more realistic. Nonetheless, the stronger assumption was deemed preferable because of the small number of objects to avoid partially degenerate solutions. (Degenerate solutions are those that

exhibit an excellent fit, but are substantively meaningless, e.g., all object points collapsing into one, and all ideal points into another.)

Unfolding analysis is a very useful technique in marketing research. It allows us to understand patterns of individual differences in preference judgments, and their relationships to product features and subjects' background information. This kind of analysis may eventually help marketing analysts to develop practical marketing strategies. Interested readers are referred to the work by Takane (2007) for more examples of application of unfolding analysis.

A Summary and Software for MDS

MDS is designed for visualization of observed (dis)similarity data by distance models. In this article, we discussed essential ingredients for practical uses of MDS, such as the distance models, fitting criteria, the data collection methods, and levels of measurement scales. We also discussed several variants of MDS (simple MDS, individual differences MDS, and unfolding analysis) with concrete

Figure 5 The joint plot of object points (asterisks) and subjects' ideal points (dots) for the preference data on the six colors presented in Table 3 (a PREFSCAL solution obtained under the interval-scaled similarity data). The objects are labeled, and the first five subjects' ideal points are numbered while the remaining ideal points are merely indicated by dots. (Some subjects' ideal points coincide.)

examples of application. For more detailed discussions on these topics, see the work by Takane *et al.* (2009).

ALSCAL (Takane *et al.*, 1977) has been in statistical packages for social sciences (SPSS) for quite a long time now. However, it is slowly being superseded by a newer program PROXSCAL (Busing *et al.*, 1997). The latter directly fits the distance model (rather than the squared distance model), allows multiple random starts (rather than a single rational start), and has better graphing features in the output.

Unfolding analysis has been a difficult one to undertake because of many instances of degenerate solutions. PREFSCAL (Busing *et al.*, 2005) seems to have largely overcome the problem by incorporating a penalty term in the optimization criterion. PREFSCAL has recently been incorporated into SPSS.

MULTISCALE, an ML MDS program, can be downloaded free online along with the program manual.

Glossary

Bayes rule – A decision procedure that minimizes the posterior expected loss.

Bonferroni inequality – The probability of at least one event in a family occurring is less than or equal to the sum of the separate probabilities that the individual events will occur.

Contrast – A weighted linear combination of parameters (usually group means), with the sum of the weights constrained to sum to zero.

Coverage rates – The measures of how often a family of confidence intervals includes their intended parameters or contrasts among parameters. Per comparison, per family, and familywise coverage rates may be defined analogously to the corresponding error rates.

Directional error rates – Any of the standard multiple comparisons error rates (per comparison error rate (PCE), per family error rate (PFE), familywise error rate (FWE), or false detection rate (FDR)) with Type I errors replaced by Type III errors.

False detection rate (FDR) – The average of the ratio of the number of Type I errors for a family of comparisons to the number of rejected null hypotheses for that family. (For replications with no rejections, this ratio is defined to be zero.)

Familywise error rate (FWE) – The probability of making at least one Type I error for a family of comparisons.

Per comparison error rate (PCE) – The average number of Type I errors for a family of comparisons, divided by the number of comparisons in the family.

Per family error rate (PFE) – The average number of Type I errors for a family of comparisons.

Type III error – The incorrect identification of the sign of a parameter or of a contrast among parameters.

It is a common situation in educational research to be making statistical inferences based on models that have more than a single parameter. The researcher's interest may be in trying to answer questions about the values of these parameters or to make comparisons among them. By its nature, statistical inference involves the possibility of error, and it is an inescapable fact that, when more inferences are made, more errors are likely to be made. This unsettling state of affairs is known as the multiple

comparisons problem. Although it was published more than 20 years ago, the best general source on multiple comparisons remains the book by Hochberg and Tamhane (1987). Other very useful resources on the subject include Hsu (1996), Miller (1981), Shaffer (1995), and Westfall *et al.* (1999).

Early studies of multiple comparisons were made by Duncan (1955), Dunnett (1955), Fisher (1935), Lehmann (1957a, 1957b), Roy and Bose (1953), Scheffé (1953), and Tukey (1953). These authors and others (see Harter (1980), for the early history of the subject) focused on the problem of multiple comparisons in the context of the analysis of variance (ANOVA). Specifically, in this setting, the comparisons are made among several group or treatment means (denoted by μ_i) for a response variable of interest. These comparisons typically take the form of statistical tests of multiple null hypotheses. For instance, it is common to consider testing $H_0: \mu_i = \mu_j$ for all pairs of group response means.

After an introduction to different measures of error rates for multiple comparisons, a review of some of the better-known procedures for carrying out multiple hypothesis tests comparing means is provided. Next, an example is introduced to illustrate the use of these procedures. Subsequent sections address the issue of directional inferences, the use of Bayesian methods for multiple comparisons, and the topic of simultaneous confidence intervals. Finally, the need for application of multiple comparisons procedures in settings beyond the analysis of variance is illustrated with an example making inferences about the elements of a correlation matrix.

Error Rates

A number of different measures of Type I errors have been considered for use with multiple hypothesis tests. The simplest of these is the per comparison error rate (PCE). It is defined as the average number (over replications) of Type I errors, divided by the total number of comparisons being made in some family of interest. If each null hypothesis for the family of comparisons is tested at some fixed level α (such as 0.05), then the PCE will be at most α (when all null hypotheses are true).

A second measure of Type I errors to be used with multiple comparisons is known as the per family error rate (PFE). For a specified family of comparisons, this is defined as the average number of Type I errors. If each of

k comparisons is tested at a fixed level α , then the PFE will be at most $k\alpha$ (again, when all tested null hypotheses are true). It must always be the case that $PCE \leq PFE$, regardless of how the comparisons are tested.

The most widely used measure of Type I errors for multiple comparisons is called the familywise error rate (FWE). It is defined as the probability of making at least one Type I error for a family of comparisons. If the tests for k comparisons are stochastically independent, and each is carried out at a fixed level α , then the FWE will be at most $1-(1-\alpha)^k$, a bound once again achieved when all the tested null hypotheses are true. If the multiple tests are not independent, there is no simple expression for the FWE. However, the Bonferroni inequality guarantees that, for any family of comparisons, the FWE can never exceed the PFE: $FWE \leq PFE$. (The Bonferroni inequality says that the probability of at least one event in a family occurring is less than or equal to the sum of the separate probabilities that the individual events will occur. Since this latter sum equals the average number of occurrences, the stated result follows immediately.)

The three error rates considered so far were all discussed by Tukey (1953). More recently, a fourth measure, known as the false detection rate (FDR), was introduced by Benjamini and Hochberg (1995). The FDR is equal to the average (over replications) of the ratio of the number of Type I errors to the number of rejected null hypotheses. (For replications with no rejected null hypotheses, this ratio is defined to be zero.) One may think of the FDR as a compromise between the PFE and the PCE. It approaches the PCE when most hypotheses are rejected on most replications. On the other hand, when few hypotheses are rejected on most replications, it approaches the PFE. It will always be the case that $PCE \leq FDR \leq PFE$.

When there is only one comparison, the corresponding test is carried out at level α , and the null hypothesis being tested is true, then $PCE = PFE = FWE = FDR = \alpha$. In this sense, all four multiple comparison error rates are generalizations of the single comparison Type I error rate.

When a family of tests is carried out, each at level α , the PCE is controlled at α for all possible configurations of true and false null hypotheses. This is not generally true for any of the other error rates. The procedures that generally control the PFE at α are those that test comparison i at level α_i with $\sum \alpha_i = \alpha$. The simplest version of this approach for a family of k comparisons sets all $\alpha_i = \alpha/k$. With m group means and a family of all pairwise comparisons, $k = m(m-1)/2$. This is often referred to as the Bonferroni procedure. Note that to demonstrate control of the PFE for all configurations of true and false null hypotheses with these procedures, no reference to the Bonferroni inequality is needed. Using the Bonferroni inequality, $FWE \leq PFE \leq \alpha$, this procedure also controls the FWE at α . The Bonferroni procedure was first proposed by Fisher (1935).

Some Multiple Comparison Procedures

Many multiple comparison procedures (MCPs) have been proposed to control the FWE at a given level α for all configurations of true and false null hypotheses for a given family of comparisons. One method that provides this control for some but not all such configurations is known as the least significant difference (LSD) procedure. It was first proposed by Fisher (1935).

The LSD MCP is a two-step procedure. In the first step, all null hypotheses in the family are tested with a single, omnibus test, such as the F -test in the one-way ANOVA setup. If this test does not reject the overall null hypothesis at level α , then stop. If it does reject, then proceed to the second step: Carry out individual tests for the family of comparisons, each at level α .

If all null hypotheses are true, the omnibus test rejects with probability α . Therefore, the probability of at least one Type I error for an individual null hypothesis in this case is at most α . In other words, when all null hypotheses are true, the LSD procedure controls the FWE at α .

Now consider an example from the one-way ANOVA. Suppose there are ten groups with 50 observations per group. Let nine of the means be identical, with one very different from the rest. Thus, the overall F -test, using 9 and 40 degrees of freedom, (almost) always rejects its null hypothesis when used at level $\alpha = 0.05$. Applying the LSD procedure, this means that $10(9)/2 = 45$ t -tests are always carried out. Of these, nine will always correctly reject their null hypotheses. The remaining 36 tests each reject their (true) null hypothesis with probability 0.05, based on a critical t -value of $t_{0.975}(490) = 1.965$. (The 490 degrees of freedom used here assumes that the pooled within groups variance estimate is used for all tests.) The probability that the largest t -statistic in absolute value will exceed this quantity is given by the studentized range (for nine means and 490 degrees of freedom) tail probability associated with $t_{0.975}(490)\sqrt{2} = 2.779$, namely $p = 0.569 = FWE$. (For more on the LSD, see Hayter, 1986.)

The failure of the LSD procedure to control the FWE for all configurations of means has led to the general advice that should not be used to make multiple comparisons. Other early proposals that display a similar failure to control the FWE for all configurations of means include Duncan's multiple range and the Newman-Keuls procedures. (See Hochberg and Tamhane, 1987.)

Two early proposals (in addition to the Bonferroni procedure) that do provide general control of the FWE are those of Scheffé and Tukey. For the one-way ANOVA, Scheffé's procedure controls the FWE for the (infinitely large) family of linear contrasts. If μ_i , $i = 1, \dots, m$, denote the group means and c_i , $i = 1, \dots, m$, with $\sum_{i=1}^m c_i = 0$ are

specified constants, then $\psi = \sum_{i=1}^m c_i \mu_i$ is a contrast. Note that pairwise differences $\mu_i - \mu_j$ are special cases of contrasts, with the constants $c_i = 1$, $c_j = -1$, and all the other constants equal to 0.

To apply Scheffé's procedure to a contrast ψ of interest, the following F -statistic is computed:

$$F_\psi = \frac{\left(\sum_{i=1}^m c_i \bar{y}_i \right)^2}{\left(\sum_{i=1}^m \frac{c_i^2}{n_i} \right) \hat{\sigma}_w^2}$$

where \bar{y}_i is the sample mean and n_i is the sample size for group i , and $\hat{\sigma}_w^2$ is the pooled within group variance estimate. This statistic is then compared with $(m-1)F_{1-\alpha} \left(m-1, \sum_{i=1}^m n_i - m \right)$. If the statistic exceeds this critical value, then the null hypothesis that $\psi = \sum_{i=1}^m c_i \mu_i = 0$ is rejected. Scheffé's procedure has the attractive feature of compatibility with the overall F -test, in the sense that the overall test leads to rejection of its null hypothesis if and only if Scheffé's procedure finds at least one significant contrast.

Tukey's multiple comparison procedure makes use of the studentized range distribution to control the FWE for making comparisons among means in a one-way ANOVA setup. Best known in the form used to make all pairwise comparisons with equal group sample sizes, Tukey's MCP may also be used for general comparisons in the equal sample size case and for all pairwise comparisons with unequal sample sizes (in which form it is called the Tukey–Kramer procedure). Here, only the Tukey–Kramer MCP is described. It has been shown (Hayter, 1984) that this procedure conservatively controls the FWE at α for all configurations of means in the one-way ANOVA setup.

The test statistic used with the Tukey–Kramer procedure to test all hypotheses of the form $H_0: \mu_i = \mu_j$ is given by

$$Q_{ij} = \frac{|\bar{y}_i - \bar{y}_j|}{\sqrt{\frac{\hat{\sigma}_w^2}{2} \left(\frac{1}{n_i} + \frac{1}{n_j} \right)}}$$

This statistic is compared with the critical value

$$Q_{1-\alpha} \left(m, \sum_{i=1}^m n_i - m \right),$$

namely the upper 100α percentile of the studentized range distribution for m means and

$$\sum_{i=1}^m n_i - m$$

degrees of freedom. Note that the test statistic Q_{ij} is equal to the absolute value of the usual t -statistic for comparing the means of groups i and j , multiplied by $\sqrt{2}$.

Many other MCPs have been proposed in the more than 50 years since Scheffé and Tukey introduced their methods. The interested reader should consult Hochberg and Tamhane (1987) for more details. Here, only one additional procedure is described, which was proposed by Benjamini and Hochberg (1995) to control the FDR.

The Benjamini–Hochberg procedure begins by obtaining p -values for all the statistics used to test a family of k hypotheses. (Denote the p -value for the i th hypothesis by p_i .) Next, these p_i 's are ordered with $p_{(1)} \leq \dots \leq p_{(k)}$. Define i_{crit} to be the largest value of $i = 1, \dots, k$, such that $p_{(i)} \leq i\alpha/k$, with $i_{\text{crit}} = 0$ if no such value exists. The null hypotheses associated with the i_{crit} smallest p -values should be rejected. Formally, this MCP has only been shown to control the FDR at α under special circumstances (such as when used with independent test statistics), but numerous simulations have supported the conjecture that it controls the FDR in more general settings.

An Example Applying MCPs

To compare the different MCPs that have been introduced, consider the example mentioned earlier: a one-way ANOVA with 10 groups and 50 observations per group. The family of interest consists of all 45 pairwise comparisons among the group means. To compare the procedures discussed here, they will all be translated into critical values for the usual t -tests (using the pooled within-groups variance from the overall analysis).

First, there is the PCE-controlling procedure, discussed earlier in connection with the LSD. (In what follows, it will be referred to as the LSD, even though the initial F -test is not used.) Here, the critical value needed to control the PCE at $\alpha = 0.05$ is just the 100(1- α /2) percentile of the Student's t distribution with 490 degrees of freedom, namely $t_{0.975}(490) = 1.965$. For the Bonferroni procedure, to control the PFE at $\alpha = 0.05$, the critical value needed for the t statistics is the 100(1- α /90) percentile of the same distribution, or $t_{0.99944}(490) = 3.475$.

Next, consider using Scheffé's procedure to control the FWE at $\alpha = 0.05$. This MCP uses an F -statistic for each pairwise comparison that is just the square of the t -statistic used by the LSD and Bonferroni procedures. In this example, the F -statistics are compared to $9F_{0.95}(9,490) = 9(1.899) = 17.091$. This is equivalent to comparing a t -statistic to the critical value $\sqrt{17.091} = 4.134$.

When Tukey's procedure is applied to control the FWE for all pairwise comparisons at $\alpha = 0.05$, the following critical value from the studentized range distribution

Table 1 A comparison of four MCPs applied to the problem of making all pairwise comparisons in a one-way ANOVA setup with 10 groups and 50 observations per group

Procedure	Critical t -value	Critical p -value	$\alpha = 0.05$ Control	Power for $d = 0.5$	Power for $d = 0.8$
LSD	1.965	0.05000	PCE	0.7037	0.9789
Tukey	3.178	0.00158	FWE	0.2507	0.7939
Bonferroni	3.475	0.00056	PFE (FWE)	0.1667	0.6997
Scheffé	4.134	0.00004	FWE	0.0528	0.4479

is needed: $Q_{0.95}(10, 490) = 4.495$. As noted earlier, this may be translated into comparing the pairwise t -statistics to $Q_{0.95}(10, 490)/\sqrt{2} = 4.495/1.414 = 3.178$.

Table 1 summarizes the results for this example. In addition to the calculations already given above, the p -value associated with each critical t -value is included. The powers of each procedure to reject a null hypothesis with effect sizes of $d = 0.5$ (Cohen's medium effect) and $d = 0.8$ (Cohen's large effect) are also included in the table (Cohen, 1988). Note the substantial drop in power that is the price paid for controlling the familywise Type I error rate for the family of pairwise comparisons, rather than simply controlling the PCE. Also note the modest power advantage enjoyed by the Tukey procedure over the Bonferroni and by the Bonferroni over the Scheffé procedure.

Finally, to apply the Benjamini–Hochberg FDR-controlling procedure (with $\alpha = 0.05$) in this setting, the pairwise difference t -statistic with the smallest absolute value would be compared to the LSD critical value of 1.965. (Equivalently, the corresponding largest p -value would be compared to 0.05.) This process would continue, comparing the ordered absolute values of the t -statistics to successively larger critical values (or the ordered p -values to successively smaller critical p -values), until the first significant result is obtained. At this point, that and all the remaining null hypotheses would be rejected. If the end of the list is reached with none of the t -statistics exceeding their respective critical values (including the largest one not exceeding the Bonferroni critical value of 3.475), then none of the pairwise null hypotheses would be rejected.

Directional Error Rates

In critical discussions of statistical hypothesis testing, many researchers have expressed dissatisfaction with the focus on rejecting a point null hypothesis. One relatively recent example is found in the paper by Jones and Tukey (2000). These authors insist that a point null hypothesis for a contrast is unrealistic in the sense that it can never be exactly true, and that incorrectly identifying the sign of the contrast, sometimes called a Type III error (Kaiser, 1960), should be of much greater concern than making a Type I error. An early treatment of directional errors in a general hypothesis testing framework is given by Lehmann (1950).

Lehmann (1957a, 1957b) and Bohrer (1979) provide useful early discussions of directional error rates for multiple comparisons.

Williams *et al.* (1999) apply this focus on directional errors to propose a modification of the FDR and the Benjamini–Hochberg procedure. Specifically, they redefine the FDR to be the average over replications of the proportion of sign declarations that are incorrect. They show that controlling the usual FDR at α is equivalent to controlling the directional FDR at $\alpha/2$ and advocate this as a general multiple comparisons strategy. Shaffer (2002) provides a general discussion of the issue of directional error rates and multiple comparisons.

Bayesian MCPs

So far, all the discussion of multiple comparisons has taken place in the framework of sampling theory inference and, specifically, using hypothesis testing within that framework. Duncan (1961, 1965) and Waller and Duncan (1969) provided an early treatment of multiple comparisons using Bayesian decision theory. Their focus was on directional errors for pairwise comparisons in what sampling theory would identify as a random-effects ANOVA setup.

Shaffer (1999) showed through a simulation study that Waller and Duncan's (1969) procedure provides control over a random-effects version of the directional FDR. (For a random-effects FDR, the FDR is averaged over sampling of true means as well as sampling of observed data.) This result is supported and extended in a paper by Lewis and Thayer (2004) where a Bayes rule based on a 0–1 loss function (rather than the linear one used in Waller and Duncan, 1969) is proved to control the random effects, directional FDR for the case of all pairwise comparisons. (A Bayes rule is a decision procedure that minimizes the posterior expected loss.) Lewis and Thayer (2009) continued this line of research, introducing a loss function closely related to the directional FDR and deriving a Bayes rule for this function. They showed through the use of simulations that, in the case of a fixed-effects ANOVA setup, their rule functions very similarly to the sampling theory procedure of Benjamini and Hochberg (1995) as modified for directional decisions by Williams *et al.* (1999).

Before leaving the topic of Bayesian multiple comparisons, it may be worth noting that some of the traditional MCPs have a natural translation in Bayesian terms once a directional approach to hypothesis testing is adopted. For example, consider the directional version of the Bonferroni procedure applied to posterior probabilities. The posterior expectation of the number of incorrect sign identifications for this procedure will be at most $\alpha/2$. By the Bonferroni inequality, the corresponding posterior probability of at least one incorrect sign identification will also be controlled at $\alpha/2$ by this MCP.

Multiple Confidence Intervals

Although the discussion of multiple comparisons so far has focused on hypothesis testing, several of the earliest writers on the subject (including Roy and Bose, 1953; Scheffé, 1953; and Tukey, 1953) also consider the problem of constructing multiple confidence intervals. Corresponding to the different error rates discussed for multiple hypothesis tests, there are different coverage rates that may be considered for multiple intervals. Thus, the per comparison coverage rate is defined as the average number of intervals containing the true value of the associated contrast, divided by the number of contrasts in the family. The per family coverage rate is simply the average number of intervals containing their contrast. A more easily interpretable quantity is the average number of intervals not containing their contrast. Finally, the familywise coverage rate is defined as the probability that all intervals in a family contain their contrasts.

In the case of a one-way ANOVA, the form of a confidence interval for a contrast $\psi = \mu_i - \mu_j$ is typically

$$\left(\bar{y}_i - \bar{y}_j - t_{\text{crit}} \sqrt{\hat{\sigma}_w^2 \left(\frac{1}{n_i} + \frac{1}{n_j} \right)}, \bar{y}_i - \bar{y}_j + t_{\text{crit}} \sqrt{\hat{\sigma}_w^2 \left(\frac{1}{n_i} + \frac{1}{n_j} \right)} \right).$$

Returning to the specific example discussed earlier (10 groups, 50 observations per group, family of all 45 pairwise comparisons), we can choose values for t_{crit} from **Table 1**. If we choose the value associated with the LSD procedure, namely $t_{\text{crit}} = 1.965$, the resulting intervals would control the per comparison coverage at the 0.95 level. If we take $t_{\text{crit}} = 3.178$, using the value for Tukey's MCP, the intervals would have a 0.95 familywise coverage. In other words, 95% of all replications would have all 45 Tukey intervals covering their contrasts.

The same coverage result holds (conservatively) for the wider intervals based on $t_{\text{crit}} = 3.475$ (the Bonferroni value) or $t_{\text{crit}} = 4.134$ (the Scheffé value). For the Bonferroni intervals, it is also true that the average number of intervals not containing their contrasts is controlled at 0.05. For the Scheffé intervals, the family may also be extended to all contrasts (not just pairwise differences) without losing its familywise coverage of 0.95.

Generalizations to Other Settings

Although almost all the work in multiple comparisons has taken place in the context of comparing means in the traditional ANOVA, it is clear that the issue has much broader implications for statistical inference. For instance, Hochberg and Tamhane (1987) include a chapter on distribution-free and robust procedures, and have sections on categorical data analysis as well as the comparison of variances. To conclude this treatment of the subject, consider the problem of making inferences about the correlations among a set of variables.

Table 2 presents a correlation matrix from an unpublished study, including all bivariate Pearson product-moment correlations among a set of 12 variables (labeled X11 through X62), based on $N = 113$ complete data records. (Actually, these are six variables, each observed at two time points.) The contents of the table are slightly edited output from a standard package of statistical programs. In particular, the output assigns stars to significant correlations: one star if significant at the 0.05 level, and two stars if significant at the 0.01 level. It should be noted that these significance levels refer to PCEs – per comparison Type I error rates.

With 12 variables, there are 66 distinct correlations. If all 66 population correlations were actually equal to zero and a PCE of 0.05 were adopted, then the PFE would be 3.3. In other words, an average of more than three correlations would be erroneously identified as significantly different from zero. Using a PCE of 0.01, the PFE would be 0.66.

The simplest MCP to apply to a set of correlations is the Bonferroni. To control the PFE (and, thus, the FWE) at 0.05, each correlation should only be judged to be significantly different from zero if the corresponding p -value is less than $0.05/66 = 0.0007576$. Based on a t -test with 111 degrees of freedom, this corresponds to declaring as significant only correlations with $|r| > 0.312$. These correlations are indicated with bold print in **Table 2**. Note that, while 31 of the 66 correlations in **Table 2** are significant using a PCE of 0.05, only 20 remain significant using a PFE of 0.05.

Finally, it may be instructive to consider the application of the Benjamini–Hochberg MCP to this problem. (It should be noted that there is no formal guarantee that this procedure will control the FDR for a family of correlations.) To carry out this procedure, it may be easiest to copy the correlations into a single column of a spreadsheet, compute the corresponding p -values (to greater precision than standard software provides), order these p -values, and, starting with the largest, compare them to the critical values $i(0.05/66)$, where i gives the rank (with $i = 66$ being the largest and $i = 1$ the smallest). When this is done, the first p -value that is less than its corresponding critical value is $p = 0.01978$, corresponding to $|r| = 0.219$. This is the 28th p -value, so the corresponding critical value is $28(0.05/66) = 0.02121$.

**Correlation is significant at the 0.01 level (two-tailed).

*Correlation is significant at the 0.05 level (two-tailed).

Bold correlations significant at the PFE 0.05 level (two-tailed) – Bonferroni.

Italic and bold correlations significant at the FDR 0.05 level (2-tailed) – B-H.

Listwise *N* = 113.

Consequently, all correlations having p -values smaller than 0.02121 are declared significant by the Benjamini–Hochberg procedure. There are an additional eight correlations (beyond those identified by the Bonferroni procedure) that are so declared. They are shown in italics in Table 2. Here, the additional significant results obtained when trying to control the FDR rather than the PFE is clearly illustrated. The Benjamini–Hochberg procedure takes advantage of the fact that there are a number of highly significant correlations in this family to declare still more correlations significant. (Remember that the FDR is the average proportion of Type I errors among the significant results.)

To make a connection with the other topics treated in this article, it should be noted that controlling the PFE with the Bonferroni procedure at the 0.05 level has the effect of controlling the directional PFE at the 0.025 level. Similarly, controlling the Type I FDR at 0.05 has the effect of controlling the directional FDR at 0.025. Working with Bayesian posterior tail probabilities for the correlations instead of sampling theory p -values in this example, the same Bonferroni and Benjamini–Hochberg operations could be applied and would result in the control of the corresponding posterior directional error rates. Finally, a set of 66 simultaneous 95% confidence intervals (or Bayesian posterior intervals) could be computed for all the correlations in this example, based on the Bonferroni procedure, by producing individual $100(1-0.05/66) = 99.924\%$ intervals for each correlation.

Multivariate Analysis of Variance

N T Longford, UPF, Barcelona, Spain

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Correlation – A scale-free measure of the dependence (association) of two variables.

Covariance – A measure of the dependence (association) of two variables.

Factor – A variable the values of which are (a small number of) categories.

Heteroscedastic – Adjective for ‘unequal variance.’

Homoscedastic – Adjective for ‘equal variance.’

Hypothesis testing – A data-based procedure for deciding whether to contradict or not to contradict a specific conjecture (hypothesis).

Multivariate – Involving several variables.

Normal distribution – A statistical distribution with a particular shape of the frequencies (density) characterized by the bell curve.

Replication – A repeated application of a data-generating process that is independent of all the previous application.

Variance – A measure of the dispersion of the values of a variable.

Introduction and Background

Many educational and behavioral phenomena have several interrelated aspects and cannot be satisfactorily observed by a single variable. When the outcome variables are correlated, studying them by analyzing one variable at a time is highly unsatisfactory; a single (simultaneous) analysis is preferred. Multivariate analysis of variance (MANOVA) is concerned with multivariate outcomes observed on subjects in groups.

MANOVA can be introduced as the obvious generalization of the analysis of variance (ANOVA) from a single to several outcome variables. In MANOVA, the vectors of outcome variables are assumed to have (possibly distinct) H -variate normal distributions in the categories or groups $k = 1, \dots, K$. The vectors have expectations $\boldsymbol{\mu}_k$, but identical variance matrices $\boldsymbol{\Sigma}$. In a typical data set, planned or realized, each of the *a priori* specified groups k is represented by a random sample from the corresponding

distribution $N_H(\boldsymbol{\mu}_k, \boldsymbol{\Sigma})$. The principal research questions relate to the expectations $\boldsymbol{\mu}_k$ and the differences $\boldsymbol{\mu}_{k_1} - \boldsymbol{\mu}_{k_2}$ ($k_1 \neq k_2$) or, more generally, to contrasts

$$c_1\boldsymbol{\mu}_1 + c_2\boldsymbol{\mu}_2 + \dots + c_K\boldsymbol{\mu}_K \quad [1]$$

where the scalars c_k are constants that add up to zero: $c_1 + \dots + c_K = 0$. A multivariate contrast is defined as

$$\mathbf{c}_1^T\boldsymbol{\mu}_1 + \mathbf{c}_2^T\boldsymbol{\mu}_2 + \dots + \mathbf{c}_K^T\boldsymbol{\mu}_K \quad [2]$$

where the $H \times 1$ vectors of constants $\mathbf{c}_1, \dots, \mathbf{c}_K$ are such that $\mathbf{c}_1 + \dots + \mathbf{c}_K = \mathbf{0}_H$, the $H \times 1$ vector of identical zeros. The (univariate) ANOVA is a special case of MANOVA, with $H = 1$.

MANOVA is much more complicated than the H ANOVAs applied separately to each outcome variable. First, unlike the scalars μ_1, \dots, μ_K in ANOVA, the vectors $\boldsymbol{\mu}_1, \dots, \boldsymbol{\mu}_K$ in MANOVA need not have a well-defined ordering, say, from the lowest to the highest. It is meaningful to ask which group k has the smallest expectation in ANOVA, whereas in MANOVA there need not be a group k such that each component of $\boldsymbol{\mu}_k$ is smaller than the corresponding component of $\boldsymbol{\mu}_{k'}$ for any other group k' . Further, MANOVA assumes not only that each variable is homoscedastic with respect to the groups (has equal within-group variances); the within-group covariances are also identical. One approach to dealing with these complications is to apply ANOVA to the combination $\mathbf{d}^T\mathbf{Y}$ of the outcome vector \mathbf{Y} , for a range of $H \times 1$ vectors of constants \mathbf{d} . An unattractive feature of this proposal is that a continuum of vectors \mathbf{d} has to be considered.

Hypothesis Testing

In MANOVA, one is usually interested whether or not the K expectations $\boldsymbol{\mu}_k$ are identical. Hypothesis testing can be interpreted as regarding equality (homogeneity) of the expectations as the default, and rejecting it only when the data contain information sufficient to contradict homogeneity. Therefore, the equality cannot be confirmed. An alternative viewpoint rejects homogeneity outright, without any data analysis, on the grounds that equality is a special case of a continuum of possible differences among the expectations $\boldsymbol{\mu}_k$; in brief, it is a safe bet that some of the expectations differ.

MANOVA considers two models. In the first, general (unrelated) within-group expectations are assumed:

$$Y = \boldsymbol{\mu} + \boldsymbol{\Delta}_k + \epsilon \quad [3]$$

where $\boldsymbol{\mu}$ and $\boldsymbol{\Delta}_k$, $k = 1, \dots, K$, are (unknown) vectors of parameters. The $\boldsymbol{\Delta}_k$ represent the differences among the within-group mean vectors $\boldsymbol{\mu}_k = \boldsymbol{\mu} + \boldsymbol{\Delta}_k$. The second model is a submodel (special case) of the first, in which all vectors $\boldsymbol{\Delta}_k$ vanish. There is an indeterminacy in [3], as a change in $\boldsymbol{\mu}$, to $\boldsymbol{\mu} + \mathbf{a}$, can be compensated by the cancelling change in each $\boldsymbol{\Delta}_k$, to $\boldsymbol{\Delta}_k - \mathbf{a}$. This problem is resolved by declaring group 1 as the reference and setting $\boldsymbol{\Delta}_1 = \mathbf{0}$. Of course, another group can be selected as the reference (or the labels $1, \dots, K$ permuted accordingly). As an alternative, we may insist on a linear constraint, such as

$$\mathbf{D}_1 \boldsymbol{\Delta}_1 + \dots + \mathbf{D}_K \boldsymbol{\Delta}_K = \mathbf{d}$$

where \mathbf{D}_k are matrices of constants and \mathbf{d} a given vector.

The test of homogeneity (equality of the expectations $\boldsymbol{\mu}_k = \boldsymbol{\mu} + \boldsymbol{\Delta}_k$) is derived from the likelihood ratio statistic and is related to the within and between-group sums of squares. Let the respective estimators based on these statistics be

$$\begin{aligned} \hat{\boldsymbol{\Sigma}}_0 &= \frac{1}{n-1} \sum_{k=1}^K \sum_{i=1}^{n_k} (\mathbf{y}_{ik} - \hat{\boldsymbol{\mu}}) (\mathbf{y}_{ik} - \hat{\boldsymbol{\mu}})^T \\ \hat{\boldsymbol{\Sigma}}_1 &= \frac{1}{n-K} \sum_{k=1}^K \sum_{i=1}^{n_k} (\mathbf{y}_{ik} - \hat{\boldsymbol{\mu}}_k) (\mathbf{y}_{ik} - \hat{\boldsymbol{\mu}}_k)^T \end{aligned}$$

Assuming that the null-hypothesis is valid,

$$\begin{aligned} (n-1)\hat{\boldsymbol{\Sigma}}_0 &\sim W_H(\boldsymbol{\Sigma}, n-1) \\ (n-K)\hat{\boldsymbol{\Sigma}}_1 &\sim W_H(\boldsymbol{\Sigma}, n-K) \end{aligned} \quad [4]$$

where $W_H(\boldsymbol{\Sigma}, m)$ denotes the H -variate Wishart distribution with variance matrix $\boldsymbol{\Sigma}$ and m degrees of freedom. Note that this distribution is for $H \times H$ symmetric (positive-definite) matrices.

The two estimators in [4] are related by the decomposition

$$(n-1)\hat{\boldsymbol{\Sigma}}_0 = (n-K)\hat{\boldsymbol{\Sigma}}_1 + \sum_{k=1}^K n_k (\hat{\boldsymbol{\mu}}_k - \hat{\boldsymbol{\mu}})(\hat{\boldsymbol{\mu}}_k - \hat{\boldsymbol{\mu}})^T \quad [5]$$

The two terms on the right-hand side are independent; we say that this decomposition is orthogonal. Under the null hypothesis, the summation in [5] has Wishart distribution with variance matrix $\boldsymbol{\Sigma}$ and $K-1$ degrees of freedom. Operating with matrix-distributions is awkward; for example, it is very difficult to define a suitable rejection or confidence region. For the determinants of the sum-of-squares matrices $T = (n-1)\hat{\boldsymbol{\Sigma}}_0$ and $W = (n-K)\hat{\boldsymbol{\Sigma}}_1$, we have the following result:

$$\Lambda = \frac{\det(\mathbf{W})}{\det(\mathbf{T})}$$

has the Wilks' Λ distribution with parameters H , $n-K$, and $K-1$. The matrices \mathbf{W} and \mathbf{T} and $\mathbf{T} - \mathbf{W}$ have Wishart distributions with variance matrix $\boldsymbol{\Sigma}$ and respective degrees of freedom $n-K$, $n-1$, and $K-1$. Provided that $n \gg K$, the transformation

$$- \left\{ n - K - \frac{1}{2}(H - K + 2) \right\} \log(X)$$

of a random variable X with Wilks' Λ distribution has approximately χ^2 distribution with $H(K-1)$ degrees of freedom. A test of homogeneity rejects the null-hypothesis for large values of this statistic.

Fixed and Random Effects

Often a given set of groups $k = 1, \dots, K$ is considered in an analysis, and each group k has a well-identified label that transcends the data set that happens to have been collected. That is, in a (hypothetical) replication of the study, each $k = 1, \dots, K$ would have the same meaning as in the realized study, and the value of $\boldsymbol{\Delta}_k$ would be unchanged. We say that the vectors $\boldsymbol{\Delta}_k$ are fixed. Replications of the study would use these unchanging values of $\boldsymbol{\Delta}_k$.

When there are only a few groups, K , their labels are usually well recognized, and so it is natural to regard $\boldsymbol{\Delta}_k$ as fixed. When there are many of them, it is natural to regard them as a realization from a superpopulation of groups, and regard $\boldsymbol{\Delta}_k$ as random. Then we have to consider a design for sampling from this superpopulation; simple random sampling is the simplest choice. This implies that $\boldsymbol{\Delta}_1$ in one replication refers in general to different groups in two distinct replications, or that the labels $k = 1, \dots, K$ are assigned arbitrarily, with no relation to the original labels (names) that the groups might have. A group that is represented in one replication need not be represented in another replication at all. Therefore, any need to make inferences about $\boldsymbol{\Delta}_1$, or another group with an *a priori* set index, is specific to the replication, and could not have arisen prior to data collection. Descriptions of the collection (superpopulation) of the groups might then be more relevant. To aid this, we declare $\boldsymbol{\Delta}_k$ as random vectors with a multivariate normal distribution

$$\boldsymbol{\Delta}_k \sim N_H(0_H, \boldsymbol{\Sigma}_B) \quad [6]$$

independently both across k and from the subject-level deviations ϵ_{ik} . Setting the expectation in [6] to zero entails no loss of generality. The matrix $\boldsymbol{\Sigma}_B$ describes the pattern of variation of the group-level deviations.

Hypotheses of interest about $\boldsymbol{\Sigma}_B$ relate to its pattern; for example, that $\boldsymbol{\Sigma}_B = 0$, that $\boldsymbol{\Sigma}_B$ is of rank 1, or that $\boldsymbol{\Sigma}_B$ is diagonal. Note that these hypotheses entail some abuse of notation because multivariate normal distribution with a singular variance matrix is not well defined. However, the

hypotheses can be reformulated in terms of normal distributions with fewer dimensions, such as $\Delta_k = D\delta_k$, where D is a $H \times H'$ matrix and $H' < H$, or these singular (degenerate) distributions could be added to the definition of the multivariate normal distribution.

An apparent advantage of the random-effects MANOVA is that each Δ_k can be estimated with greater efficiency than by the sample mean $\hat{\boldsymbol{\mu}}_k$. The conditional distribution of Δ_k given the model parameters $\boldsymbol{\mu}$, Σ , and Σ_B and the data y is

$$(\Delta_k | y; \boldsymbol{\mu}, \Sigma, \Sigma_B) \\ \sim N_H \{ \boldsymbol{\mu} + \Sigma_B(\Sigma + n_k \Sigma_B)^{-1}(\hat{\boldsymbol{\mu}}_k - \boldsymbol{\mu}), n_k \Sigma_B(\Sigma + n_k \Sigma_B)^{-1} \Sigma_B \} \quad [7]$$

The expectation of this distribution can be estimated by replacing the parameters it involves with their estimates. The estimated (conditional) expectation is a suitable estimator of Δ_k ; we denote it by $\tilde{\Delta}_k$. Then $\hat{\boldsymbol{\mu}}_k = \hat{\boldsymbol{\mu}} + \tilde{\Delta}_k$ is a suitable estimator of $\boldsymbol{\mu}_k$.

The estimators $\tilde{\Delta}_k$ and $\hat{\boldsymbol{\mu}}_k$ can be interpreted as (multivariate) compositions of $\hat{\boldsymbol{\mu}}_k$ and $\hat{\boldsymbol{\mu}}$, with weights assigned to $\hat{\boldsymbol{\mu}}_k$ and $\hat{\boldsymbol{\mu}}$ that reflect their precisions. For example, if Σ_B (or $\hat{\Sigma}_B$) is very small, then $\tilde{\Delta}_k = \hat{\boldsymbol{\mu}}$. This should come as no surprise; since Σ_B is small, the vectors of expectations differ very little from one another, and so they differ very little from $\boldsymbol{\mu}$. Therefore, $\hat{\boldsymbol{\mu}}$ is a good estimator of $\boldsymbol{\mu}_k$. When Σ_B is large, in the sense of large variances and eigenvalues, the vectors $\boldsymbol{\mu}_k$ tend to differ a lot from one another, and so $\hat{\boldsymbol{\mu}}$ is a poor estimator of $\boldsymbol{\mu}_k$, and we cannot improve on $\hat{\boldsymbol{\mu}}_k$. In intermediate settings, choosing between $\hat{\boldsymbol{\mu}}_k$ and $\hat{\boldsymbol{\mu}}$ is not a good strategy; combining these two estimators, as done in $\hat{\boldsymbol{\mu}}_k$, is much more efficient. The univariate version of this approach is commonly referred to as borrowing strength across the groups. It amounts to exploiting the similarity of the groups.

Estimating Σ

The between-group variance Σ_B is estimated by moment matching. We form the average sum of squares of deviations

$$S_B = \frac{1}{K-1} \sum_{k=1}^K (\hat{\boldsymbol{\mu}}_k - \hat{\boldsymbol{\mu}})(\hat{\boldsymbol{\mu}}_k - \hat{\boldsymbol{\mu}})^T$$

and adjust it to make it unbiased for Σ_B . Standard manipulations yield the identity

$$E(S_B) = \Sigma_B + \frac{1}{K-1} \Sigma \sum_{k=1}^K g_k$$

where $g_k = 1/n_k - 1/n$. Hence, the unbiased estimator

$$\hat{\Sigma}_B = S_B - \frac{1}{K-1} \hat{\Sigma} \sum_{k=1}^K g_k$$

This estimator is problematic when the sample sizes n_k are very uneven. An alternative estimator

$$S_B^\dagger = \frac{1}{n} \sum_{k=1}^K n_k (\hat{\boldsymbol{\mu}}_k - \hat{\boldsymbol{\mu}})(\hat{\boldsymbol{\mu}}_k - \hat{\boldsymbol{\mu}})^T$$

takes the sample sizes into account, but the estimator it yields,

$$\hat{\Sigma}_B^\dagger = S_B^\dagger - \frac{D-1}{n} \hat{\Sigma}$$

is biased. The bias depends on the association of the sample sizes with the deviations $\boldsymbol{\mu}_k - \boldsymbol{\mu}$. The advantages and drawbacks of $\hat{\Sigma}_B$ and $\hat{\Sigma}_B^\dagger$ depend on the level of imbalance (variation of n_k), but are also highly contingent on the assumption of normality. A composition of the two estimators may be a good compromise, but the weights have to be chosen with care.

Multiway MANOVA

The variable that indicates the group to which a subject is assigned is called a factor. In a study, there may be several factors, such as age groups and the two sexes in a study of a human population. The consistent (systematic) differences among the levels of either of these two factors can be described by the model

$$y_{ikl} = \boldsymbol{\mu} + \Delta_k^{(1)} + \Delta_l^{(2)} + \varepsilon_{ikl} \quad [8]$$

where y_{ikl} is the vector of outcomes for subject $i = 1, \dots, n_{kl}$ in group $k = 1, \dots, K$ of the first factor and group $l = 1, \dots, L$ of the second factor, and ε_{ikl} are a random sample from $N(0_H, \Sigma)$. The groups (levels) k and l of the two factors are associated with respective parameter vectors $\Delta_k^{(1)}$ and $\Delta_l^{(2)}$. Lack of identifiability is dealt with by setting $\Delta_1^{(1)}$ and $\Delta_1^{(2)}$ to 0_H . The model in [8] assumes that the average difference between two groups of one factor, conditional on the value of the other factor (i.e., with the other factor fixed), does not depend on the latter. This assumption can be relaxed by introducing interactions of the two factors. This is equivalent to introducing a single factor with the KL categories formed by pairing every category of one factor with each category of the other factor.

Two factors A and B are said to be crossed if there is at least one category of A that contains units from at least two categories of B and there is at least one category of B that contains units from at least two categories of A. For example, in a typical setting, age groups and sex are crossed factors, because there are subjects from several (or all) categories of age group among both males and females and there are males and females in most (or all) age categories. Factor A is said to be nested within factor B, if each category of A is contained within a category of B. For example, in a typical country, district as a factor is

nested within region as a factor, because each district belongs to a region.

The design of a one-way MANOVA is said to be balanced if each group k has the same sample size n_k . The design of a two-way MANOVA with crossed factors is said to be balanced if each combination of categories k and l of the two factors has the same sample size n_{kl} . For a nested design, with factor A nested within factor B, balance amounts to the same number of categories of A within each category of B and identical sample sizes n_k for each category of A. Balanced designs are associated with efficiency and yield simple estimators.

Inference About the Pattern in Σ

Apart from inference about the within-group means μ_k and their counterparts in multi-way MANOVA, for which a lot of theory carries over from the univariate ANOVA, the covariance structure of within-group variance matrix Σ may also be of interest. For example, Σ may have the compound symmetry form

$$\Sigma = \sigma^2(\mathbf{I}_H + \rho \mathbf{1}_H \mathbf{1}_H^T)$$

where $\sigma^2 > 0$ and ρ are unknown parameters and \mathbf{I} is the identity matrix, so that all variances in Σ are equal to $(1 + \rho)\sigma^2$ and all covariances to $\rho\sigma^2$.

When the vector Y is a time series, its Markovian nature, the conditional dependence of any two components given the intervening observations,

$$Y_{b_1} \perp Y_{b_2} \mid Y_b,$$

for any indices $b_1 < b < b_2$, may be of interest. This pattern of dependence corresponds to tri-diagonal matrix Σ^{-1} .

The universal approach to testing the hypotheses related to these submodels is by the likelihood ratio test, which compares the values of the likelihood at their maxima for the hypothesis and the alternative. However, the counting of the degrees of freedom is problematic when an estimated variance matrix is singular, because the solution is on the boundary of the parameter space.

Example

The following problem has been studied in educational assessment. An educational test, comprising a small number of distinct sections (subtests), is administered in US institutions. These institutions are subscribers (volunteers), and each institution arranges for (some of) its students to take part. The purpose of the test is to assess the relative strengths and weaknesses of each institution in the subject areas represented by the subtests.

MANOVA models can be applied to this setting, with the institution-level vectors of mean subscores, and their contrasts, as the targets of inference. If these vectors are well ordered or their components highly correlated, an institution with a high mean score on one subtest has a high mean score also on the other. Reporting the (sample) subscore means then adds little or no information to reporting the overall mean. In two studies dealing with different testing programs, it was observed that the heterogeneity of the students is substantial, and therefore a large number of students from an institution is required to find any evidence that institutions have different patterns of the subscore means. Since these numbers exceed the numbers of enrolled students in most institutions, the tests are of doubtful value for the intended purpose. The voluntary nature of participation of students within institutions, which may lead to poor representation of the institution by the test-takers, raises further statistical challenges.

Other applications of MANOVA include analysis of growth and development, repeated measurements (as a way of combatting measurement error), and analysis of all characteristics and attributes that cannot be satisfactorily captured by a single variable.

Glossary

Canonical correlation analysis – A technique to explain or summarize the relationship between two sets of variables by finding a linear combination of each set of variables that yields the highest possible correlation between the composite variable for set A and the composite variable for set B .

Dependent and independent variables –

Statistical models normally specify how one set of variables, called dependent variables, functionally depend on another set of variables, called independent variables. The term '(in)dependent' reflects only the functional relationship between variables within a model.

MANOVA – Multivariate analysis of variance, a generalized form of analysis of variance (ANOVA), is a technique which determines the effects of independent variables on multiple continuous dependent variables, and is generally used to compare several groups with respect to multiple continuous variables.

Method of least squares – A well-founded technique for estimating the unknown parameters in a linear regression model, based on minimization of the sum of squared differences between observed and modeled responses.

Multivariate regression – Multivariate (linear) regression is a technique aimed at finding a linear relationship between many response variables and multiple explanatory variables.

Regression analysis – It provides a best-fit mathematical equation for the relationship between the response variable(s) and regressor variable(s) or covariates.

Wilks' lambda – A general test statistic used in multivariate tests (e.g., MANOVA) based on a combination of dependent variables. Several other statistics are special cases of Wilks' lambda.

In many scientific studies, numerous variables (or measurements) are obtained for each individual or unit studied. Regression analysis is a statistical methodology for predicting the value of one (or more variables) from a collection of other variables. Regression models have been used extensively in the education literature (see, e.g., Hsu, 2005).

In the simplest case, we may be interested in studying the relationship between two sets of variables, say, Y_1, Y_2, \dots, Y_q and X_1, X_2, \dots, X_p , in particular, a linear relationship between them. This approach is the well-known linear-regression modeling, where we assume that the variables Y 's are dependent on the variables X 's. Although in a general linear modeling framework, both the Y 's and the X 's could be quantitative (or metric) and qualitative (or nonmetric), the most practical and commonly used case of linear-regression modeling assumes both the Y 's and the X 's to be quantitative in nature.

In statistical terminology, Y 's are called the response (or dependent or target or output) variables and X 's are known as the regressor (or explanatory or independent or predictor or input) variables.

We may consider three distinguished cases, also indicated by Rencher (2002), according to the number of response and regressor variables:

1. *Simple linear regression.* Here, the interest is on one response Y and one regressor X ; for example, predicting college freshman grade-point average (GPA) based on the student's SAT score.

Usually, a model is postulated by relating the response variable to the regressor variable with unknown parameters. A model that is linear in these parameters is called the simple linear regression model. This model, also referred to as a straight line model, is fitted via a technique known as the least squares and takes the form $Y = \beta_0 + \beta_1 X$, where β_0 and β_1 are the so-called intercept and slope parameters. The reader may read any intermediate-level statistics textbook for further details (e.g., Ott and Longnecker, 2001).

2. *Multiple linear regression.* Multiple regression analysis is used whenever we wish to model the relationship between one response variable and more than one regressor variable. In the preceding example, we could attempt to improve our prediction of college GPA by using, for example, high school GPA, Scholastic Aptitude Test (SAT) scores, and rating of school.

Many different forms of relationship are possible, but the overwhelming emphasis in practical applications is on the linear relationship $Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_p X_p$, known as the multiple linear regression model. The regression coefficients $\beta_0, \beta_1, \dots, \beta_p$ are model parameters whose values need to be estimated from the given data.

3. *Multivariate (multiple) linear regression.* Multivariate multiple regression analysis arises when we have more than one response variable, and we wish to model the relationship between these variables and a set of regressor variables. Attention is again focused almost exclusively on linear relationships. In the preceding example, we may wish to predict freshman college GPA (in the sciences, arts, and humanities) as well as the number of years of college the student will complete based on high school GPA, SAT, and rating of school.

Note that, in multivariate multiple linear regression, multivariate refers to the response variables and multiple represents the independent variables so that (2) above can be regarded as univariate linear regression. The focus of this article is on multivariate linear regression and the main aim is to give a detailed exploration of the topic including examples.

A mathematical formulation of the multiple linear regression model is provided in this article, with relationship to univariate (multiple) linear regression and the method of least squares. The underlying assumptions are discussed and model diagnostics carried out. This article also covers testing of hypotheses, ANOVA partitioning, and simultaneous confidence intervals. The application of the fitted models is illustrated via an example and suitable computer software.

Even though most of the basic theory behind the topic of interest, multivariate linear regression, is generally available in many textbooks and research articles, the following account is based on the seminal work of Khattree and Naik (1995) and Krzanowski (1998).

Formulation of the Multivariate Linear Regression Model

Suppose that we observe, say, q response variables Y_1, \dots, Y_q and p regressor variables X_1, \dots, X_p on, say, n sample individuals or units. Here, we shall focus on the behavior of response variables in terms of the regressor variables. The regressor variables are usually assumed to be measured without error, but the response variables are subject to measurement errors.

Furthermore, the regressor variables may be fixed or random. In the above examples, all X 's are random variables in that a student is selected at random and all the Y 's and X 's are measured for that individual (so, the variables are not under the control of the researcher). In some cases, especially in experimental situations, the X 's are fixed so that they are under the control of the researcher. For example, we may wish to relate, say, yield and the nutritional value of corn to various levels of a certain fertilizer and several varieties. Here, the amounts of fertilizer to be applied and the choices of variety are controlled by the

researcher who then observes the changes in the yield and nutritional responses. We shall interpret the regression model conditional on the type of regressor variables. A detailed account of modeling when the regressors are fixed and when they are random, is given by Rencher (2002).

In the univariate case, the linear regression model is defined by the following equation:

$$y_k = \beta_0 + \beta_1 X_{k1} + \beta_2 X_{k2} + \dots + \beta_p X_{kp} + \varepsilon_k \quad [1]$$

Here, y_k is the response for the k th individual in the given sample, X_{kj} is the value of the j th regressor variable for the k th individual, and ε_k is the random departure term for that individual representing the measurement errors. Since random sampling is assumed, the ε_k 's are taken to be independent and identically distributed random variables, each having mean zero and constant variance σ^2 .

If we collect together all the y_k , β_j , and ε_k into the vectors (with superscript T denoting matrix transposition) $\mathbf{y} = (y_1, y_2, \dots, y_n)^T$, $\boldsymbol{\beta} = (\beta_0, \beta_1, \dots, \beta_p)^T$, and $\boldsymbol{\varepsilon} = (\varepsilon_1, \varepsilon_2, \dots, \varepsilon_n)^T$, and write the regressor variable values in the $n \times (p+1)$ regressor matrix

$$\mathbf{X} = \begin{pmatrix} 1 & X_{11} & \dots & X_{1p} \\ 1 & \vdots & \ddots & \vdots \\ 1 & X_{n1} & \dots & X_{np} \end{pmatrix}$$

then, the above model [1] can be written in the compact form

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \quad [2]$$

In this formulation, $\boldsymbol{\varepsilon}$ is a random vector whose mean is $\mathbf{0}$ ($n \times 1$ vector of zeroes) and whose dispersion (or covariance matrix) is $\sigma^2 \mathbf{I}_n$, \mathbf{I}_n being the $n \times n$ identity matrix, implying that the ε_k 's are identically and independently distributed with mean 0 and variance σ^2 .

In the multivariate situation, that is, when there are more than one response variable, we have to allow each Y_i to have its own linear relationship with all the X_j 's. Thus, we have to specify q different linear models, one between each Y_i and the set of X_j . By analogy with the above eqn [2], we can write these models as

$$\mathbf{y}_i = \mathbf{X}\boldsymbol{\beta}_i + \boldsymbol{\varepsilon}_i \quad [3]$$

where $\mathbf{y}_i = (y_{i1}, y_{i2}, \dots, y_{in})^T$, $\boldsymbol{\beta}_i = (\beta_{i0}, \beta_{i1}, \dots, \beta_{ip})^T$, and $\boldsymbol{\varepsilon}_i = (\varepsilon_{i1}, \varepsilon_{i2}, \dots, \varepsilon_{in})^T$, for $i = 1, \dots, q$.

Here, y_{ik} is the value observed for the i th dependent variable on the k th sample unit, ε_{ik} is the error term corresponding to the i th dependent variable and k th individual, $(p+1) \times 1$ vector $\boldsymbol{\beta}_i$ are the parameters corresponding to the i th dependent variable, and \mathbf{X} is the same matrix as before.

In fact, the q equations in [3] can be represented compactly via the following matrix notation:

$$Y = XB + \xi \quad [4]$$

where the q vectors y_i are put side by side as columns into the $n \times q$ matrix Y , say, the response matrix, the q vectors β_i similarly into the $(p+1) \times q$ matrix B as columns, say, the parameter matrix, and the q column vectors ϵ_i into the $n \times q$ matrix ξ , say, the error matrix.

It is possible to treat each of the q equations in [3] independently of each other as a univariate linear regression. However, since the response variables may themselves be correlated with each other, this dependence should also be taken into account when fitting the multivariate linear regression model. This, indeed, suggests the need for using the model in eqn [4], where all the dependent variables are analyzed together. Even though the regression parameter estimates and their standard errors from the multivariate approach should be identical to those obtained from the set of univariate models, the added advantage with the multivariate regression model is that it allows for joint inferences involving two or more of the univariate models. For example, one may test the overall significance of the regression parameters (across all fitted univariate models) using a single statistical test. Furthermore, one may also test whether the coefficients of a particular regressor are the same across all fitted (univariate) models. Such hypotheses tests are explained later in this article.

Once again, the n sample individuals are assumed to be independent, but now there is an association among the error terms $\epsilon_{k1}, \dots, \epsilon_{kq}$ ($k = 1, \dots, n$) corresponding to the same individual. Consequently, we can treat the rows of the error matrix ξ as independent observations from a distribution with mean vector zero and dispersion matrix, say, Σ , and for most practical purposes, this distribution is assumed to be multivariate normal. In other words, while the i th column of ξ has the covariance matrix, say, $\sigma_{ii}^2 I_n$, I_n being the $n \times n$ identity matrix, a typical row of ξ has that as, say, $\sum = [\sigma_{ij}]$, a symmetric $q \times q$ matrix that is assumed to be positive definite, where given X , $\text{cov}(Y_i, Y_j) = \text{cov}(\epsilon_i, \epsilon_j) = \sigma_{ij} I_n$, for $i, j = 1, \dots, q$. The assumption of multivariate normality for error vectors is needed for hypothesis testing and construction of confidence regions, even though it is not needed for estimating parameters in the multivariate regression modeling.

Fitting the Multivariate Linear Regression Model via Least-Squares Estimation

Maximizing the likelihood for the model in eqn [4] under the normality condition produces an estimator of B given by

$$\hat{B} = (X^T X)^{-1} X^T Y \quad [5]$$

The same estimator results from the simple process of minimizing the criterion error sum of squares

(and products) via the well-known least-squares approach. To demonstrate, we wish to minimize,

$$\sum_{i=1}^q \epsilon_i^T \epsilon_i = \sum_{i=1}^q (y_i - X\beta_i)^T (y_i - X\beta_i)$$

where y_i , β_i , and ϵ_i are as defined before. This is equivalent to minimizing the trace (i.e., sum of diagonal elements) of the $p \times p$ matrix $(Y - XB)^T (Y - XB)$, which results in a set of normal equations,

$$(X^T X)B = X^T Y$$

Solving these equations yield the estimator \hat{B} , given by eqn [5], as the least squares estimator of parameter matrix B .

Note that, as in the univariate linear regression case, we assume that the regressor matrix X is of full rank, that is, $\text{rank}(X) = p+1$. This implies the existence of $(X^T X)^{-1}$ as $\text{rank}(X^T X) = \text{rank}(X)$. Although a generalized inverse of $(X^T X)$ may be used when X is not of full rank, extra care is needed when interpreting the regression results in such situations.

Moreover, since we may write $\hat{B} = [\hat{\beta}_0 \hat{\beta}_1 \dots \hat{\beta}_q]$, using appropriate columns from eqn [5],

$$\hat{\beta}_i = (X^T X)^{-1} X^T y_i \text{ for } i = 1, \dots, q \quad [6]$$

It is easy to observe that \hat{B} is an unbiased estimator of B , that is, $E(\hat{B}) = B$. Furthermore, we can show

$$\text{cov}(\hat{\beta}_i, \hat{\beta}_j) = \sigma_{ij} (X^T X)^{-1} \text{ for } i, j = 1, \dots, q \quad [7]$$

Equation [6] appears to imply that the regression coefficients in the multivariate linear regression model have the same estimates as they would if each response variable was regressed separately on the entire set of regressor variables, that is, when fitting univariate linear regression models. However, this may not be as simple as it sounds due to the fact that all the individual $\hat{\beta}_{ij}$ in \hat{B} are inter-correlated in the case of multivariate regression modeling. In other words, those $\hat{\beta}_{ij}$ within a column of \hat{B} are correlated because of possible correlations among the regressor variables, and those in different columns of \hat{B} because of the correlations among the response variables.

Hence, instead of performing statistical inference (hypothesis tests, etc.) separately on each β_i , that is, in a univariate regression scenario for response variable Y_i , we should perform multivariate tests of hypotheses, etc., about the regressor matrix B . This, in fact, would allow testing of hypotheses with respect to parameters within univariate models as well as between such models.

Statistical Inference

The hypothesis tests associated with the regression parameters in B are the analogs in multivariate analysis of

variance (MANOVA) of the analysis of variance (ANOVA) F -tests for univariate linear (multiple) regression. The general theory behind MANOVA is beyond the scope of this article, but can be found elsewhere in the encyclopedia and in many textbooks on multivariate analysis, for example, Krzanowski (2000).

Here, we shall simply specify the relevant matrices from which the test statistics are obtained, and by analogy with univariate linear regression. The total variation associated with the response variables is given by the $p \times p$ matrix of (mean-corrected) total sums of squares and products (SSP) defined as

$$\mathbf{T} = \mathbf{Y}^T \mathbf{Y} - n \bar{\mathbf{y}} \bar{\mathbf{y}}^T \quad [8]$$

where $\bar{\mathbf{y}} = [\bar{y}_1, \bar{y}_2 \dots \bar{y}_q]^T$ is the matrix of sample mean vectors of the $\mathbf{y}_i = (y_{i1} \ y_{i2} \dots y_{in})^T$, $i = 1, \dots, q$. Note here that the ij th element of \mathbf{T} corresponds to the sample covariance between the i th and j th response variables (i.e., the mean-corrected SSP divided by appropriate degrees of freedom).

Assuming that the regressor matrix \mathbf{X} is of full-rank $p + 1$, the total matrix \mathbf{T} can be partitioned into the hypothesis matrix, say, \mathbf{H} for testing the overall significance of regression and the error or residual matrix, say, \mathbf{E} . The \mathbf{H} and \mathbf{E} matrices, in the expression $\mathbf{T} = \mathbf{H} + \mathbf{E}$, are given by

$$\mathbf{H} = \hat{\mathbf{B}}^T \mathbf{X}^T \mathbf{Y} - n \bar{\mathbf{y}} \bar{\mathbf{y}}^T \quad [9]$$

and

$$\mathbf{E} = \mathbf{Y}^T \mathbf{Y} - \hat{\mathbf{B}}^T \mathbf{X}^T \mathbf{Y} = (\mathbf{Y} - \mathbf{X} \hat{\mathbf{B}})^T (\mathbf{Y} - \mathbf{X} \hat{\mathbf{B}}) \quad [10]$$

Note that, while $\hat{\mathbf{Y}} = \hat{\mathbf{B}} \mathbf{X}$ is the matrix of the predicted values, the diagonal elements of the matrices \mathbf{T} , \mathbf{H} , and \mathbf{E} , respectively, represent the usual total, regression and error sums of squares for the corresponding dependent variables in the univariate linear regression scenario. Furthermore, eqn [10] implies that an unbiased estimate of Σ is given by $\mathbf{E}/(n-p-1)$.

Testing of (Linear) Hypotheses: Multivariate Tests

In the context of multivariate linear regression models, the hypotheses examined may be, in general, associated with the functions of the regressor matrix \mathbf{B} . Here, we aim to test the redundancy of certain regressor variables, or use the tests in connection with model-reduction schemes as in the process of selecting regressor variables, or when a comparison of two or more populations is needed (where the regressor variables are regarded as experimental factors).

The most popular general form of such (linear) hypotheses is

$$H_0: \mathbf{LBM} = \mathbf{0} \text{ vs } H_1: \mathbf{LBM} \neq \mathbf{0}$$

where $\mathbf{0}$ denotes the matrix of zeroes, and, say, \mathbf{L} is a matrix of size $r \times (p + 1)$, and \mathbf{M} is a $q \times s$ matrix. \mathbf{L} may be regarded as defining a linear function on the regressor side and \mathbf{M} as defining a linear function on the response side.

The \mathbf{L} and \mathbf{M} matrices play different roles. So, they need to be chosen carefully: \mathbf{L} is used to obtain a linear function of the regression parameters within the models, thus, leading to, for example, testing the significance of a single regressor or difference between two regressors associated with each of the response variables; \mathbf{M} , on the other hand, is used for testing the significance of a linear function of regression parameters associated with different response variables but corresponding to the same set of regressors, for example, testing the difference between the coefficients of, say, X_1 in the models for Y_1 and Y_2 . Hence, using both \mathbf{L} and \mathbf{M} would lead to interesting inferences.

When we wish to test only the hypotheses associated with regression parameters, \mathbf{M} is set as the $q \times q$ identity matrix. Similarly, when the significance of the entire multivariate regression model fitted is tested, matrix \mathbf{L} is also set as an identity matrix of size $(p + 1) \times (p + 1)$.

The corresponding hypothesis and error matrices are then given by

$$\mathbf{H} = \mathbf{M}^T \hat{\mathbf{B}}^T \mathbf{L}^T [\mathbf{L}(\mathbf{X}^T \mathbf{X})^{-1} \mathbf{L}^T]^{-1} \hat{\mathbf{L}} \mathbf{B} \mathbf{M} \quad [11]$$

and

$$\mathbf{E} = \mathbf{M}^T (\mathbf{Y}^T \mathbf{Y} - \hat{\mathbf{B}}^T \mathbf{X}^T \mathbf{Y}) \mathbf{M} \quad [12]$$

There are many test statistics available to test the hypotheses stated above, most being based on the functions of eigenvalues, say, $\lambda_1, \lambda_2, \dots, \lambda_q$, of the matrix $\mathbf{H} \mathbf{E}^{-1}$, assuming \mathbf{E}^{-1} exists. These include:

1. Roy's maximum root: The largest eigenvalue, say, λ_{\max}
2. Hotelling-Lawley trace:

$$\sum_{i=1}^q \lambda_i = \text{Trace}(\mathbf{H} \mathbf{E}^{-1})$$

3. Pillai's trace:

$$\sum_{i=1}^q \frac{\lambda_i}{1 + \lambda_i} = \text{Trace}(\mathbf{H}(\mathbf{H} + \mathbf{E})^{-1})$$

4. Wilks' lambda:

$$\prod_{i=1}^q \frac{1}{1 + \lambda_i} = \frac{|\mathbf{E}|}{|\mathbf{H} + \mathbf{E}|}.$$

(see Krzanowski (2000) or Khattree and Naik (1995) for further details.)

Note that, Pillai's trace may be regarded as a measure of response variable variation explained by the fitted multivariate linear regression model, and as an analog to the well-known coefficient of determination (R^2) in the context of univariate linear regression.

Although many comparisons of these statistics have been considered in the literature, the results are still indecisive. However, the Wilks' lambda statistic (usually denoted by Λ) has been chosen by many researchers, partly because of its ease of computation, but mainly for the existence of distributional approximations which enable critical values to be readily found. Hence, the remainder of this article considers only the Wilks' lambda test statistics.

Although tables of critical values for this and other test statistics are available, we shall explore the popular F -statistic approximation for Wilks' lambda given by

$$F = \left(\frac{1 - \Lambda^{1/t}}{\Lambda^{1/t}} \right) \left(\frac{st - 2u}{ab} \right) \quad [13]$$

where

$$s = (n - p - 1) - \frac{b - a + 1}{2}, a = \text{rank}(\mathbf{L}), b = \text{rank}(\mathbf{H} + \mathbf{E}), \\ u = (ab - 2)/4$$

and

$$t = \begin{cases} \sqrt{(a^2 b^2 - 4)/(a^2 + b^2 - 5)} & \text{if } (a^2 + b^2 - 5) > 0 \\ 1 & \text{otherwise} \end{cases}$$

The F -statistics in eqn [13] is said to approximately follow an F -distribution with degrees of freedom ab and $(st - 2u)$. The distribution is exact if $\min(a, b) \leq 2$ (see Rao (1973) for details).

Furthermore, if in particular $\mathbf{H}_0: \mathbf{LB} = \mathbf{0}$ (with $\mathbf{M} = \mathbf{I}_q$) is rejected, then we may attempt to provide further inference on the regression parameters. For example, we may compute confidence intervals for the individual components of \mathbf{LB} or just \mathbf{B} (if $\mathbf{L} = \mathbf{I}_{p+1}$). Here, we use Roy's largest eigenvalue statistic in conjunction with the corresponding (approximate) F -distribution (see Khattree and Naik (1995) for further details).

Example and Software

To illustrate the basic theory and ideas above, we shall consider the following example (hereafter referred to as the SAT data):

DASL (see Web resources) describes data from 1994–95 for each of the 50 US states, for the variables current expenditure per pupil in thousands of dollars (COST), the average pupil/teacher ratio (RATIO), the estimated average annual salary of teachers in thousands of dollars (SALARY), the percentage of all eligible students taking the SAT (ELIGIBLE), then average verbal SAT score (VERBAL), the average math SAT score (MATH), and the average total score on the SAT (TOTAL). Additional information on this data can be

found in Guber (1999). It is quite natural to think of linear modeling to predict verbal and math SAT scores for a set of values of COST, RATIO, SALARY, and ELIGIBLE, even though these regressor variables were not fixed by the investigator.

The main aim here is to fit a multivariate linear regression model expressing response variables VERBAL and MATH as linear functions of regressor variables COST, RATIO, SALARY, and ELIGIBLE, and to carry out some hypothesis testing related to the regression parameters as well as the response variables.

Recall that, in matrix notation, the model is given by $\mathbf{Y} = \mathbf{XB} + \boldsymbol{\xi}$, where we may define matrices \mathbf{Y} , \mathbf{X} , \mathbf{B} , and $\boldsymbol{\xi}$ as $\mathbf{Y} = [\mathbf{y}_{\text{VERBAL}} \ \mathbf{y}_{\text{MATH}}]_{50 \times 2}$, $\mathbf{X} = [\mathbf{1} \ \mathbf{x}_{\text{COST}} \ \mathbf{x}_{\text{RATIO}} \ \mathbf{x}_{\text{SALARY}} \ \mathbf{x}_{\text{ELIGIBLE}}]_{50 \times 5}$, and $\boldsymbol{\xi} = [\boldsymbol{\varepsilon}_{\text{VERBAL}} \ \boldsymbol{\varepsilon}_{\text{MATH}}]_{50 \times 2}$, with $\mathbf{y}_{\text{VERBAL}}$, \mathbf{x}_{COST} etc. being the response and regressor vectors of size 50×1 (50 representing the US states), $\mathbf{1}$ being a 50×1 vector of 1s and the 50×1 vectors $\boldsymbol{\varepsilon}_{\text{VERBAL}}$ and $\boldsymbol{\varepsilon}_{\text{MATH}}$ representing the error respective errors; and

$\mathbf{B} = [\boldsymbol{\beta}_{\text{VERBAL}} \ \boldsymbol{\beta}_{\text{MATH}}]_{5 \times 2}$ with, say, $\boldsymbol{\beta}_{\text{VERBAL}} = (\beta_{V_{\text{Int}}} \ \beta_{V_{\text{COST}}} \ \beta_{V_{\text{RATIO}}} \ \beta_{V_{\text{SALARY}}} \ \beta_{V_{\text{ELIGIBLE}}})^T$ and $\boldsymbol{\beta}_{\text{MATH}} = (\beta_{M_{\text{Int}}} \ \beta_{M_{\text{COST}}} \ \beta_{M_{\text{RATIO}}} \ \beta_{M_{\text{SALARY}}} \ \beta_{M_{\text{ELIGIBLE}}})^T$ representing the regression parameters.

Suppose we wish to test the following hypotheses:

- \mathbf{H}_{01} : significance (overall) of the entire model;
- \mathbf{H}_{02} : significance of each of the regressor variables;
- \mathbf{H}_{03} : coefficients or parameter estimates associated with regressors COST and SALARY are the same for each of the response variables VERBAL and MATH (or are the same in the two equations given by eqn [3]).

We may rewrite the above hypotheses in the form $\mathbf{H}_0: \mathbf{LBM} = \mathbf{0}$ with $\mathbf{H}_{01}: \mathbf{B} = \mathbf{0}$, where $\mathbf{M} = \mathbf{I}_{2 \times 2}$ and $\mathbf{L} = \mathbf{I}_{5 \times 5}$ $\mathbf{H}_{02}: \mathbf{LBM} = \mathbf{0}$, where $\mathbf{M} = \mathbf{I}_{2 \times 2}$ and $\mathbf{L} = (0 \ 1 \ 0 \ 0 \ 0)_{1 \times 5}$ for testing the significance of regressor variable COST, $\mathbf{L} = (0 \ 0 \ 1 \ 0 \ 0)_{1 \times 5}$ for testing the significance RATIO, etc.

$\mathbf{H}_{03}: \mathbf{LBM} = \mathbf{0}$, where $\mathbf{M} = \begin{pmatrix} 1 \\ -1 \end{pmatrix}_{2 \times 1}$ and $\mathbf{L} = \begin{pmatrix} 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \end{pmatrix}_{2 \times 5}$

or equivalently, test $\beta_{V_{\text{COST}}} - \beta_{M_{\text{COST}}} = 0$ and $\beta_{V_{\text{SALARY}}} - \beta_{M_{\text{SALARY}}} = 0$ simultaneously.

Statistical computing software packages, such as SAS (2002–03) and R (2008), may be used readily to carry out a multivariate linear regression analysis and test specific hypotheses such as those mentioned above. We shall utilize the SAS system via coding to perform the required analyses. For a basic introduction to using SAS for statistical analyses, see Der and Everitt (2002).

The annotated SAS codes are presented in Table 1. The well-known regression procedure PROC REG of SAS has been used here with additional statement MTEST for carrying out multivariate tests (e.g., Wilks' lambda with F -approximation). Though PROC REG also produces the regression parameter estimates automatically, for those interested in using matrix manipulations for the various

(Further details are available from the author, in particular, on the use of PROC IML.)

computations, SAS provides the powerful PROC IML procedure. As an example, PROC IML codes for computing the regression parameter estimates given by $\hat{\mathbf{B}}$ in eqn [5], is also shown in **Table 1**. The estimates are given by $\hat{\mathbf{B}} = [\hat{\boldsymbol{\beta}}_{\text{VERBAL}} \hat{\boldsymbol{\beta}}_{\text{MATH}}]_{5 \times 2}$, with $\boldsymbol{\beta}_{\text{VERBAL}} = (509.699 \ 1.307 \ -2.081 \ 0.630 \ -1.337)^T$ and $\boldsymbol{\beta}_{\text{MATH}} = (536.272 \ 3.156 \ -1.543 \ 1.008 \ -1.567)^T$.

Table 2 shows the relevant portions of the edited output obtained by running the PROC REG codes in **Table 1**. We noted earlier that the regression coefficients in the multivariate linear regression model have the same estimates as they would if each response variable was regressed separately on the entire set of regressor variables (in univariate linear regression models), as supported by eqn [6]. The first part of **Table 2** shows these univariate regression results indicating that with no

restrictions (i.e., just estimating the regression parameters using eqn [5]), the estimated regression relationships to be $\text{VERBAL} = 509.699 + 1.307 \times \text{COST} - 2.081 \times \text{RATIO} + 0.627 \times \text{SALARY} - 1.337 \times \text{ELIGIBLE}$.

$\text{MATH} = 536.272 + 3.156 \times \text{COST} - 1.543 \times \text{RATIO} + 1.008 \times \text{SALARY} - 1.567 \times \text{ELIGIBLE}$.

We can see that the regression coefficients obtained here are exactly the same as those obtained via matrix manipulations shown above. The significance of these regression coefficients, given by the corresponding p values in **Table 2**, are based on the univariate regression approach. So, they need to be interpreted with caution! Ideally, the significance of each of the regression parameters should be examined in a multivariate sense, that is, overall with respect to the two response variables, and these results, obtained via PROC REG codes, are shown below.

Table 2 also shows the estimated error SSP matrix \mathbf{E} and the regression or hypothesis SSP matrix \mathbf{H} (given by eqns [9] and [10]) associated with the null hypothesis H_{01} , that is, for testing the significance of the entire fitted model. Interpretation of these matrices is left to the reader's discretion. The corresponding Wilks' lambda-based multivariate test (labeled overall model) indicates that the approximate F-statistic with 10 and 88 degrees of freedom has a very large value of 291.14 and a very small p value of <0.0001 , thus, providing very strong evidence for significance of the entire multivariate linear regression model fitted.

The multivariate tests (labeled COST, RATIO, SALARY, and ELIGIBLE) for testing the significance of each regressor variable simultaneously among all the response variables indicate that, only the variable ELIGIBLE has a very significant effect on the variables VERBAL and MATH. This is indicated by the F-statistic (78.20) for the corresponding Wilks' lambda with very small p -value (<0.0001). The F-statistics for each regressor has the same degrees of freedom, and the other regressors COST, SALARY, and RATIO all appear to not significantly contribute to VERBAL and MATH.

Finally, consider testing of the hypothesis that the parameter estimates associated with regressors COST and SALARY are the same for each of the response variables VERBAL and MATH. The corresponding F-statistic with 2 and 45 degrees of freedom derived from Wilks' lambda has a value 3.47 and a p -value of 0.0348 (see multivariate test labeled SameCoef). Thus, at best, the hypothesis could only be rejected with weak evidence, indicating that COST and SALARY have approximately the same coefficients in the linear regression models for VERBAL and MATH.

Note here that, the advantage of fitting a multivariate regression model (or bivariate regression model in the above example) over fitting separate (or two, in the example) univariate regression models is that, in general, the former takes into account the correlation(s) between the response variables while the latter ignores such interdependency. To illustrate, consider a hypothesis testing similar

to the last one above. Here, suppose we wish to compare the coefficients of regressor variable COST for the two regression models fitted, one for response VERBAL and the other for MATH. We may construct a test statistic synonymous with a two-sample t -test when using two separate univariate models, assuming independence between the response variables. On the other hand, using a bivariate/multivariate regression model would yield us a testing process synonymous with the so-called paired t -test. However, we know that, when the assumption of independence is in question, the paired t -test is more powerful than the two-sample t -test. Hence, it is logical to conclude that multivariate regression modeling is more powerful than fitting separate univariate regression models when the correlation structure between the response variables are considered to be an important aspect of the modeling process.

Summary

Linear regression models, in general, are among the most commonly used statistical methods, while multivariate regression models extend the basic idea to many response variables. The theory behind multivariate linear regression modeling is highly developed and easily applied to real problems. Implementation or fitting of multivariate linear regression models is more difficult than fitting a univariate linear regression model, but procedures are readily available in statistics software packages such as SAS and R.

This article provided an easily digestible theory on multivariate linear regression modeling illustrated by an easily understood example. It also focused on modeling with quantitative response and regressor variables. The analysis of models with qualitative regressor variables

with quantitative responses is usually covered in a MANOVA scenario with experimental factors. The case with qualitative responses and quantitative regressors could be tackled via the typical discrimination and classification scenarios, but the case where both the response and regressor variables are qualitative, may be handled by techniques such as canonical correspondence analysis. Many of the above scenarios are also covered in the area of generalized linear models. Another technique that has a very close relationship with multivariate linear regression is known as canonical correlation analysis (CCA). CCA provides a symmetric relationship between the response and regressor variables and attempts to extract most of the association between the two sets of variables via the linear functions of the two sets (Krzanowski, 2000).

The reader is referred to Kharttree and Naik (1995) and Rencher (2002) for an extended coverage on multivariate linear regression modeling, including model diagnostics, response surface modeling, simultaneous confidence intervals, handling fixed and random regressor variables, and dealing with nonsingular matrices leading to the use of generalized inverses.

Multivariate Normal Distribution

J Tacq, Catholic University of Brussels, Brussels, Belgium

© 2010 Elsevier Ltd. All rights reserved.

Elsewhere in the encyclopedia, there is a discussion about univariate normal distribution. This article describes multivariate normal distribution, the case with multiple variables. Univariate normal distribution is defined by two parameters, mean and variance. When multiple variables are involved, we must cope with a vector of means (i.e., a centroid) rather than deal with a single mean, and with a covariance matrix which contains variances (on the principal diagonal) and also covariances (off-diagonal) in place of a single variance. Consequently, the problem becomes considerably more complex, although the basic principles remain the same.

Bivariate Normal Distribution

A special case of the multivariate normal distribution is the bivariate normal distribution with only two variables, so that we can show many of its aspects geometrically. (For more than two variables it becomes impossible to draw figures.) The probability density function of the univariate normal distribution contained two parameters: μ and σ . With two variables, say X_1 and X_2 , the function will contain five parameters: two means μ_1 and μ_2 , two standard deviations σ_1 and σ_2 and the product moment correlation between the two variables, ρ . The probability density function (pdf) of the bivariate normal distribution is given by

$$f(x_1, x_2) = \frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}} \exp \left[-\frac{1}{2}(\mathbf{x} - \boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1} (\mathbf{x} - \boldsymbol{\mu}) \right].$$

The constant term can be written in a more compact notation, if we notice that the determinant of the covariance matrix, $|\boldsymbol{\Sigma}|$, simplifies to $\sigma_1^2 \sigma_2^2 (1 - \rho^2)$. Indeed, $\boldsymbol{\Sigma}$ contains on its principal diagonal the variances σ_1^2 and σ_2^2 and on its off-diagonal the covariance $\rho\sigma_1 \sigma_2$, where its determinant is equal to $\sigma_1^2 \sigma_2^2 - \rho^2 \sigma_1^2 \sigma_2^2 = \sigma_1^2 \sigma_2^2 (1 - \rho^2)$:

$$\boldsymbol{\Sigma} = \begin{bmatrix} \sigma_1^2 & \rho\sigma_1\sigma_2 \\ \rho\sigma_1\sigma_2 & \sigma_2^2 \end{bmatrix}, |\boldsymbol{\Sigma}| = \sigma_1^2 \sigma_2^2 (1 - \rho^2)$$

Thus, the pdf of the bivariate normal distribution can also be expressed as

$$f(x_1, x_2) = (2\pi)^{-1} |\boldsymbol{\Sigma}|^{-1/2} \exp \left[-\frac{1}{2}(\mathbf{x} - \boldsymbol{\mu})' \boldsymbol{\Sigma}^{-1} (\mathbf{x} - \boldsymbol{\mu}) \right].$$

We can see that this pdf displays a general bell-shaped appearance. It looks like a mountain of normal

distribution curves. The surface is centered at the point (μ_1, μ_2) , that is, the centroid. For each point on the bottom X_1, X_2 plane, we have a point $f(X_1, X_2)$ lying on the surface of the bell-shaped mountain (Figure 1).

Conditional Distribution and Marginal Distributions

The conditional distribution $f(X_1 | X_2)$, which is the distribution of X_1 given X_2 , is usually defined as the joint distribution divided by the marginal: $f(X_1 \text{ and } X_2)/f(X_2)$. The latter, the marginal distribution of X_2 , is just the probability distribution of X_2 ignoring information about X_1 (by either summing over or integrating out X_1). For the marginal distribution of X_1 it is just vice versa: it is the probability distribution of X_1 ignoring information about X_2 (by either summing over or integrating out X_2). We can give an idea of the graphical representation of the marginal distribution of X_2 by making the orthogonal projection of the joint distribution onto the plane $X_1 = 0$ at the edge. For the marginal distribution of X_1 it is again vice versa: we make the orthogonal projection of the joint distribution onto the plane $X_2 = 0$ at the edge.

The joint density function is shown in Figure 1. For the marginal density function in Figure 2, the orthogonal projection of the joint function onto the edge plane is shown to give the reader an idea. To give a graphical representation of the conditional distribution as the division of the joint and the marginal, Figure 3 shows the joint distribution for a particular value $X_2 = 5$, divided by the marginal.

Equal-Density Contours

The place, shape, and orientation of the mountain of normal distribution curves are governed by the five parameters. The center of the mountain is determined by the centroid, that is, the vector of means. Depending on the standard deviations and the correlation, the mountain will have the shape of a circle, an ellipse, or a tilted ellipse. This can be seen if we slice horizontally through the bivariate normal surface with a plane parallel to the bottom X_1, X_2 plane. By raising and lowering this cutting plane, we obtain a series of concentric ellipses, which are places with equal height, that is, equal probability, which is why they are called equal-density contours. (An equal

density contour is a set of points for which the square of the distance to the centroid is equal to c^2 , where c is a constant.) If $\sigma_1 = \sigma_2$ and $\rho = 0$, then these equal-density contours become circles. If the standard deviations are unequal, they become ellipses whose major and minor axes are parallel to the bottom X_1, X_2 axes. If ρ is not equal to zero, the ellipses become tilted. The ellipses as equal-density contours are shown in the **Figure 4(a)–(h)**,

first as a mountain with horizontal slices and next from top, once with $\sigma_1 = \sigma_2$ and $\rho = 0$ (circles), once with $\sigma_1 \neq \sigma_2$ and $\rho = 0$ (ellipses) and once with $\sigma_1 \neq \sigma_2$ and $\rho \neq 0$ (tilted ellipses).

It is of interest to note that all kinds of calculations can be made when making use of these equal-density contours. They represent an ellipse so that the square of the distance from a point x on it to the centroid μ is constant,

Figure 1 Joint bivariate normal density function.

Figure 2 Marginal distributions (as projections).

Figure 3 Conditional distribution (joint divided by marginal).

that is, $(x - \mu)' \Sigma^{-1} (x - \mu) = c^2$. It can be shown that $(x - \mu)' \Sigma^{-1} (x - \mu)$ is distributed as chi-square with p degrees of freedom, where p is the number of variables (here, $p = 2$). So, the choice $c^2 = \chi^2_{\alpha}$, that is, the upper $(100\alpha)\%$ th percentile of the chi-square distribution, leads to a contour that contains $(1 - \alpha) \times 100\%$ of the probability. **Figure 4(a)–(h)** below shows eight such equal-density contours.

Higher values of the correlations between X_1 and X_2 are represented by thinner ellipses, whereas lower values would be represented by fatter ellipses that enclose a larger proportion of the population. Next to the case above with $\rho = 0.6$, we show an extra case below with $\rho = 0.92$.

Important Properties

Some properties of the multivariate normal distribution are often used when dealing with statistical models and methods. These properties make it possible to manipulate multivariate normal distributions easily.

Notice that all these properties hold when random vector \mathbf{X} has a multivariate normal distribution, but that the reverse does not hold, for if we have a vector that satisfies one or more of these properties (such as a marginal distribution which is univariate normal), then it is possible that it does not have a multivariate normal distribution.

The key properties of a random variable \mathbf{X} having a multivariate normal distribution are:

- Linear combinations of x -variables from vector \mathbf{X} , that is, $\mathbf{a}'\mathbf{X}$, are normally distributed with mean $\mathbf{a}'\mu$ and variance $\mathbf{a}'\Sigma\mathbf{a}$. This includes the property that the marginal distributions of x -variables from vector \mathbf{X} is normal (see exercise below).
- All subsets of x -variables from vector \mathbf{X} have a multivariate normal distribution. This also includes the property of normal marginals.
- Zero covariance between x -variables from vector \mathbf{X} implies that they are independently distributed.
- The conditional distributions of x -variables from vector \mathbf{X} are multivariate normal. This includes the special case of vector \mathbf{X} being bivariate normal, from which follows that the conditional distribution of X_1 for a fixed value of X_2 is univariate normal. The formulas of mean and variance of this conditional density are $\mu_1 + \frac{\sigma_{12}}{\sigma_{22}}(x_2 - \mu_2)$ and $\sigma_{11} - \frac{\sigma_{12}^2}{\sigma_{22}}$, respectively (see exercise below).

Central Limit Theorem

We recall from the article on univariate normal distribution, which was defined by two parameters, mean and variance, that the central limit theorem was very important. This theorem tells us that the sampling distribution of the sample

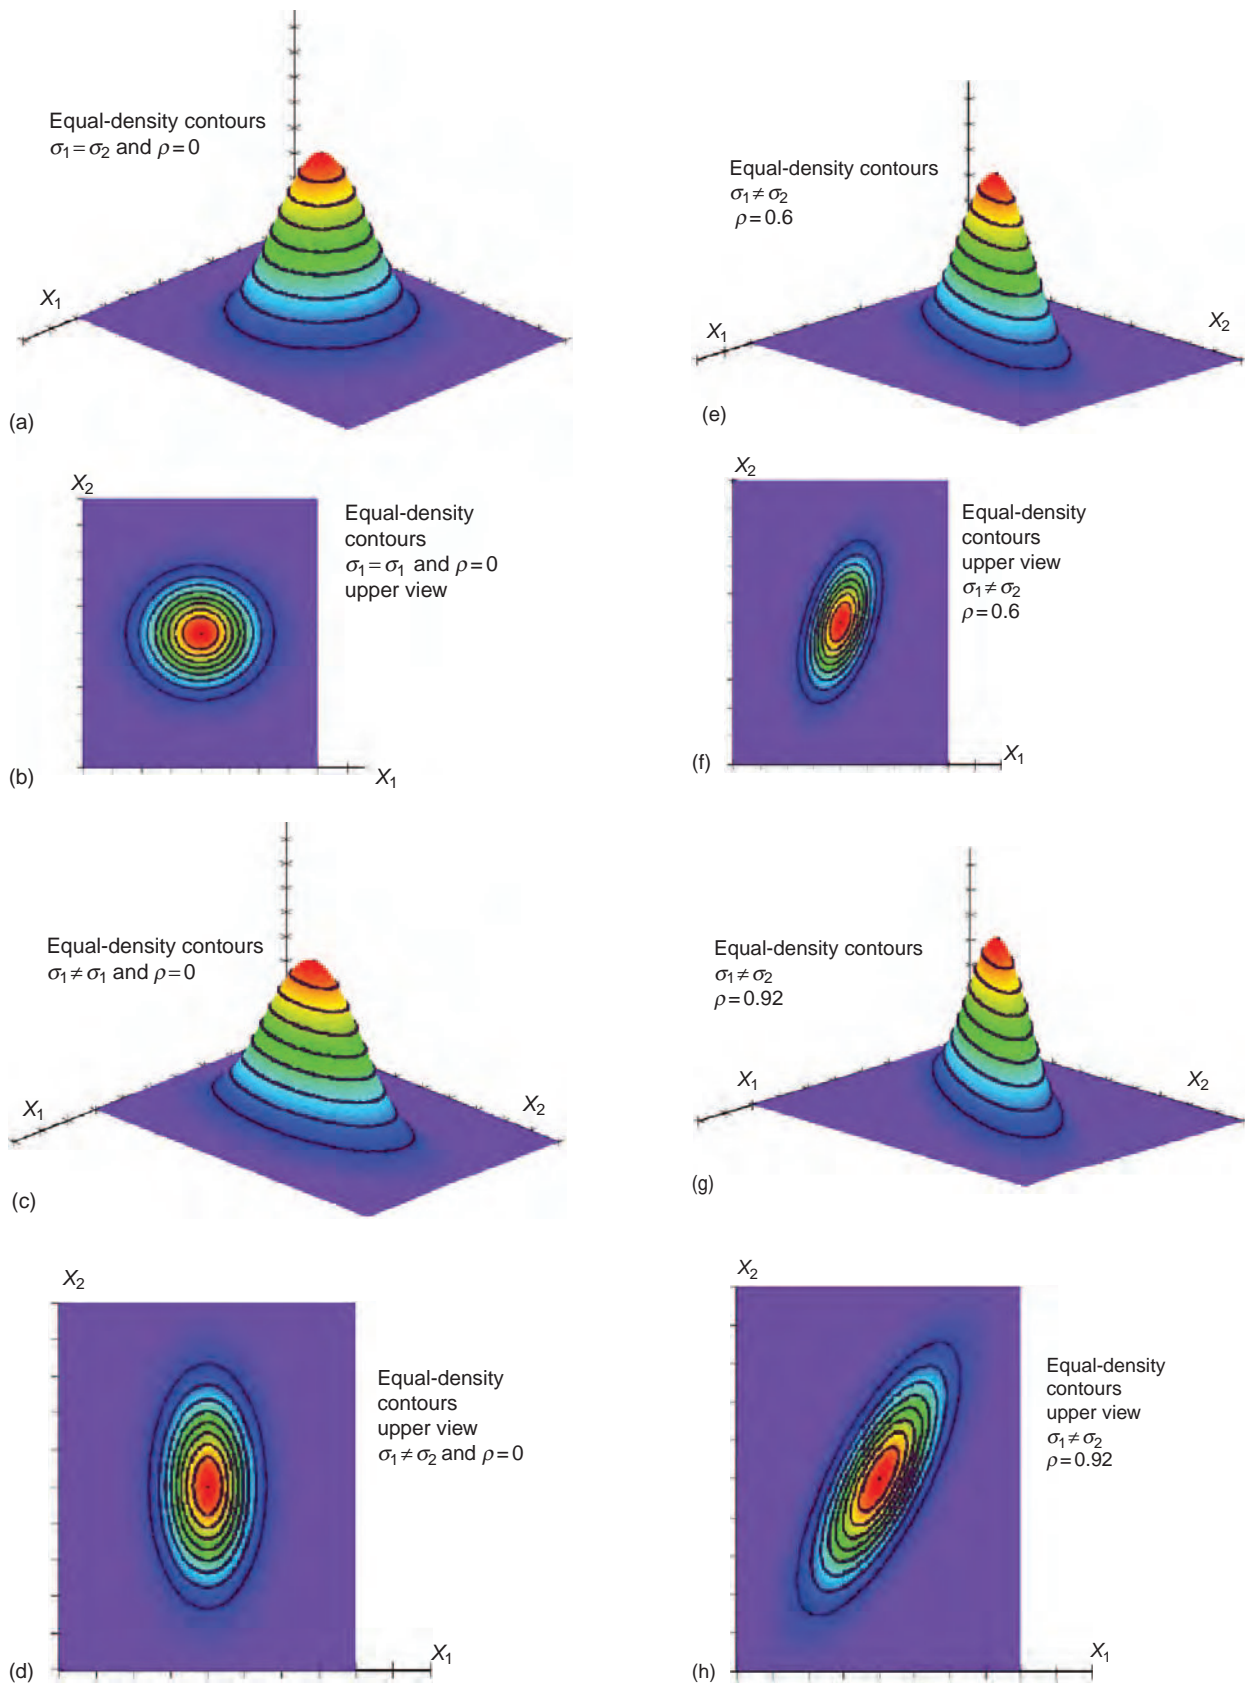

Figure 4 Equal-density contours for the bivariate normal distribution with different σ 's and ρ .

mean, \bar{X} , for a large sample size, is nearly normal, whatever the form of the underlying population distribution (with mean equal to μ , which is the mean of the population, and squared standard error equal to $(1/n)(\sigma^2)$, which is the variance of the population divided by n). It turns out that this theorem can be generalized for the multivariate case: as the sample size is increased, the sampling distribution of the centroid (vector of means) will be multivariate normal, irrespective of the form of the parent population (with centroid equal to μ , which is the centroid of the population, and covariance matrix equal to $(1/n)\Sigma$, which is the population covariance matrix divided by n). As we already mentioned, this central limit is the main cause of the immense popularity of the normal distribution and its multivariate counterpart.

Standardized Distributions and Calculation Examples

If X_1 and X_2 are standardized to z -scores with zero mean and unit standard deviation, we have, analogous to the univariate case, the standardized bivariate normal distribution. Thus

$$f(z_1, z_2) = (2\pi)^{-1} |\mathbf{R}|^{-1/2} \exp \left[-\frac{1}{2} \mathbf{z}' \mathbf{R}^{-1} \mathbf{z} \right],$$

where \mathbf{R} is the correlation matrix of $\mathbf{X} = (X_1, X_2)$. Just like in univariate normal distribution, where we can find areas under the standard normal curve, we shall be able to do the same type of thing with the bivariate normal density. Instead of areas we will now calculate volumes enclosed by the bivariate normal surface. In so doing, we can make probability statements about observations drawn randomly from a bivariate normal distribution with certain parameters.

An Example

Statistician Karl Pearson carried out a study on the resemblances between parents and children. He measured the heights of 1078 fathers and sons, and found that the fathers and sons joint heights approximately followed a bivariate normal distribution with the mean of the fathers' heights = 5 feet, 9 inches ($\mu_1 = 172.5$ cm); mean of sons' heights = 5 feet, 10 inches ($\mu_2 = 175$ cm); standard deviation of fathers' heights = 2 inches ($\sigma_1 = 5$ cm); standard deviation of sons' heights = 2 inches ($\sigma_2 = 5$ cm); correlation between fathers and sons' heights $\rho = 0.5$. (1) Predict the height of the son of a father who is 6'2" (185 cm) tall. (2) What is the probability of obtaining an observation in which the height of the son is more than the height of the father?

The solution is as follows:

1. In this numerical example we consider a bivariate normal density function with the following parameters: $\mu_1 = 172.5$ cm, $\mu_2 = 175$ cm, $\sigma_1 = 5$ cm, $\sigma_2 = 5$ cm,

$\rho = 0.5$. To predict the height of the son of a father who is 6'2" (185 cm) tall, we have to look at the conditional bivariate normal density function $f(X_2 | X_1 = 185)$, which is a univariate normal pdf of X_2 conditioned upon X_1 being held constant at 185 (see properties). From probability calculus we know that for two events A and B, the probability of B given A is obtained by dividing the joint by the marginal: $p(B|A) = p(A \text{ and } B)/p(A)$. Analogously we have $f(X_2 | X_1) = f(X_1, X_2)/f(X_1)$. The formula of the joint bivariate normal density function can be written algebraically as follows:

$$f(x_1, x_2) = \frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}} \exp \left[-\frac{1}{2(1-\rho^2)} \left\{ \frac{(x_1 - \mu_1)^2}{\sigma_1^2} - \frac{2\rho(x_1 - \mu_1)(x_2 - \mu_2)}{\sigma_1\sigma_2} + \frac{(x_2 - \mu_2)^2}{\sigma_2^2} \right\} \right]$$

This pdf has to be divided by $f(X_1) = \frac{1}{\sigma_1\sqrt{2\pi}} \exp \left(-\frac{(x_1 - \mu_1)^2}{2\sigma_1^2} \right)$. A little bit of algebra shows that this conditional distribution $f(X_2 | X_1)$ is univariate normal with expected value (mean) $= \mu_2 + (\sigma_{12}/\sigma_1^2)(X_1 - \mu_1) = 175 + ((0.5)(5)(5)/25)(185 - 172.5) = 181.25$ cm. Hence, 181.25 cm is the best prediction of the height of the son (of a father of 185 cm tall).

2. In order to prepare the second exercise we first look at the property that linear combinations of x -variables from vector \mathbf{X} , that is, $\mathbf{a}'\mathbf{X}$, are normally distributed with mean $\mathbf{a}'\mu$ and variance $\mathbf{a}'\Sigma\mathbf{a}$. An example of such a linear combination is the difference between the two variables of our bivariate normal distribution, X_1 and X_2 , where \mathbf{a}' is equal to $[1 \ -1]$. It follows that this difference $X_1 - X_2$ has a univariate normal distribution with mean $\mathbf{a}'\mu = [1 \ -1] \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix} = 172.5 - 175 = -2.5$ and variance $\mathbf{a}'\Sigma\mathbf{a} = [1 \ -1] \begin{bmatrix} 25 & 12.5 \\ 12.5 & 25 \end{bmatrix} \begin{bmatrix} 1 \\ -1 \end{bmatrix} = 25$.

Now we can easily solve the question of finding the probability of obtaining an observation in which the height of the son is more than the height of the father, i.e., $X_2 > X_1$, for this is equal to the probability that the difference $X_1 - X_2$ is smaller than zero. We know that the difference $X_1 - X_2$ has a univariate normal distribution with mean -2.5 and variance 25 , whence we have reduced the problem to a univariate case. The standard deviation of $X_1 - X_2$ is $\sigma = \sqrt{25} = 5$. Its mean is -2.5 . We want the probability $p(X_1 - X_2 < 0)$. The standardized score is $(0 - (-2.5))/5 = 0.5$. The probability $p(X_1 - X_2 < 0)$ is equal to $p(z < 0.5) = 0.69$. So, there is a probability of 69% of obtaining an observation in which the height of the son is more than the height of the father.

Although a computation involving a multivariate normal distribution can often be reduced to one involving

a simpler univariate normal distribution (as we have seen in the exercises above), it may not always be possible. Some computations with the multivariate normal distribution would invariably involve integral calculus, because volumes under the mountain of normal distributions would have to be determined. For example, if one is interested in the probability of father's height being smaller than a and son's height smaller than b , it is given by $p(X_1 < a, X_2 < b) = \int_{-\infty}^a \int_{-\infty}^b f(X_1, X_2) dx_1 dx_2$, and bivariate integral calculus has to be used in the computation. Fortunately, several statistical software packages perform such computations.

An Application: Hotelling's T^2 -Test and Mahalanobis' Distance D^2

In statistics, especially in multivariate analysis, there are many applications in which multivariate normal distribution plays an important role. Of course, linear regression analysis and its extension, structural equation models, are the example, because normality lies at the heart of these techniques. Other examples are discriminant analysis, multivariate analysis of variance, and canonical correlation analysis. Take for example discriminant analysis. For a number of groups, two or more than two, we will examine whether there is a significant difference between the centroids of the groups. If there are two groups, this is an extension of Student's T -test; if there are more than two groups, it is an extension of Fisher's F -test. We concentrate on the case of two groups (in which Hotelling's T^2 will be developed as a special case of Wilks' Λ) and we emphasize testing (rather than predicting group membership).

In Student's T -test there are two groups and only one variable. In such a univariate case, we know that the sampling distribution of the sample mean is normal if the distribution of the population from which the sample is taken is normal, and even if the distribution of the population is not normal, on the condition that the sample is sufficiently large.

In Student's T -test, the t statistic is calculated as $t = |\bar{X}_{(0)} - \bar{X}_{(1)}| / (\frac{\sigma_w^2}{n_0} + \frac{\sigma_w^2}{n_1})^{1/2}$, in which n_0 and n_1 are the group sizes and σ_w^2 (which has to be estimated!) is the pooled average of the two variances (the variance $\sigma_{(0)}^2$ of X in group 0 and the variance $\sigma_{(1)}^2$ of X in group 1) and $(\frac{\sigma_w^2}{n_0} + \frac{\sigma_w^2}{n_1})^{1/2}$ is the standard error of the sampling distribution of differences of means.

The formula of its square t^2 can be written as follows:

$$\begin{aligned} t^2 &= (\bar{X}_{(0)} - \bar{X}_{(1)})^2 / (\frac{\sigma_w^2}{n_0} + \frac{\sigma_w^2}{n_1}) \\ &= \frac{n_0 n_1}{n_0 + n_1} (\bar{X}_{(0)} - \bar{X}_{(1)}) \frac{1}{\sigma_w^2} (\bar{X}_{(0)} - \bar{X}_{(1)}) \end{aligned}$$

Hotelling constructed a statistic, called Hotelling's T^2 , in which multiple discriminating variables are included, in

which a difference of group means now becomes a difference of group centroids, because there are several variables, and in which division by the estimated variance is replaced by multiplication by the inverse of a covariance matrix containing not only the dispersions but also the mutual associations between the discriminating variables:

$$T^2 = \frac{n_0 n_1}{n_0 + n_1} \mathbf{d}' \Sigma_w^{-1} \mathbf{d}$$

Here n_0 and n_1 are again the group sizes and Σ_w is the pooled average of the two covariance matrices Σ_0 and Σ_1 . The vector \mathbf{d} is the difference vector between group centroids. The part $\mathbf{d}' \Sigma_w^{-1} \mathbf{d}$ in the formula of Hotelling's T^2 is Mahalanobis' distance D^2 .

In this multivariate case it holds, analogously, that the sampling distribution of the sample centroid is multivariate normal if the population is multivariate normal and/or if the sample is sufficiently large (which is just an extension of the central limit theorem). Under this assumption of multivariate normality, Hotelling has proven that the value $[(n - p - 1)/p(n - 2)] T^2$ is distributed as F with p and $n - p - 1$ degrees of freedom. So it becomes straightforward to test whether there is a significant difference between the centroids of two groups, that is, between the means of the many variables, taken together and taking their variances and correlation coefficients into consideration. The assumption of multivariate normality can be guaranteed by a large sample. For small samples it has to be tested.

Testing for Multivariate Normality

One should keep in mind that the multivariate normal distribution does not belong to reality, but is an idealtype. In the nineteenth century, Max Weber defined an idealtype as an exaggeration of the mind, which does not occur in the world, but with which events of the world are confronted and compared, some resembling this idealtype and others deviating from it.

Multivariate normality tests check a given set of empirical data for similarity to the idealtype multivariate normal distribution, the null hypothesis being that the data set is similar to the multivariate normal distribution; therefore a sufficiently small p -value indicates deviation from multivariate normality. Multivariate normality tests are often extensions of the well-regarded Kolmogorov–Smirnov and Shapiro–Wilk tests for univariate normality. They include the Cox–Small test and Smith and Jain's adaptation of the Friedman–Rafsky test. In a recent overview, Mecklin and Mundfrom (2004) mention that at least 50 procedures for testing multivariate normality exist, but that the state of the art is not very refined and that little work has been done in evaluating the quality and power of the procedures. They conclude that no single method is sufficient, but that a mixture of methods, that is, graphical

approaches, measures of skewness and kurtosis, and more mathematically sophisticated procedures, are likely to be the most useful.

Unfortunately, tests of multivariate normality are not really multivariate in the literal sense of the word. This is because the comparison of an empirical mountain with an idealtypic mountain is not possible. We have to rely on the properties of normal distributions, such as the property that all linear combinations of normal variables are normal and the knowledge that the contours of the multivariate normal density are ellipsoids. So, instead of comparing mountains – the empirical one and the idealtypic one – we will check whether the marginal distributions and linear combinations of x -variables are normal and whether observations of pairs of x -variables show the elliptical appearance of the equal-density contours. Another possibility is that we look for outliers in the empirical data. As Johnson and Wichern (1992: 177) state, we must pay a price for concentrating on univariate and bivariate examinations of normality. We can never be sure that we have not missed some feature that is revealed only in higher dimensions. It is possible, for example, to construct a non-normal bivariate distribution with normal marginals. But they add, first, that many types of non-normality are often reflected in the marginal distributions and scatter plots, and moreover, that for most practical work, one-dimensional and two-dimensional investigations are ordinarily sufficient.

An example of univariate test is the Q–Q-plot. Such a plot can be made for the marginal distributions of the sample observations on each variable. They are in effect plots of the sample quantile versus the quantile one would expect to observe if the observations actually were normally distributed. The plot of these pairs of points should then lie very nearly along a straight line.

One can also calculate the correlation coefficient r_Q between the sample quantiles and the quantiles expected under normality and test this correlation between empirical Q and idealtypic Q for significance. An improved version of this r_Q approach is given by Shapiro and Wilk, who replace the quantiles expected under normality by a function of the expected value of standard normal-order statistics and their covariances.

For the investigation of more than one characteristic, statisticians mostly suggest plotting the x -variables against the eigenvectors resulting from an evaluation of the eigenstructure of the sample covariance matrix.

As mentioned above, it is also possible to check whether observations of pairs of x -variables show the elliptical appearance of the equal density contours. The idea is that for observations which were generated from a multivariate normal distribution, each bivariate distribution would also

be normal (see properties) and that the contours of constant density would be ellipses. Therefore, a scatterplot should exhibit an overall pattern that is approximately elliptical. Moreover, we should expect approximately the same percentage P of sample observations to lie in the ellipse given by $(x - \mu)' \Sigma^{-1} (x - \mu) \leq \chi^2(P)$, where we have to replace μ and Σ by their estimates. As this is a rather rough procedure, it has been replaced by a more formal method based on the squared generalized distances (see Johnson and Wichern, 1992: 184 ff). This is also the case for another approach, the detection of outliers. Hawkins (1980) gives an extensive treatment of the subject of outliers.

Glossary

Curvature – The curvature measures how a geometric object deviates from being flat. There are various definitions of curvature depending on the context. In nonlinear regression analysis, the relative curvature array developed by Bates and Watts is a widely used approach for assessing curvature and nonlinearity.

Gauss–Newton method – The Gauss–Newton algorithm as a modification of Newton’s method is used to solve nonlinear least-squares problems. It is based on iterative local linear approximation to the regression function and does not require to evaluate the second derivatives.

Intrinsic nonlinearity – Intrinsic nonlinearity refers to a quantity which makes the prediction biased in nonlinear models. The degree of intrinsic nonlinearity is determined by the model and data and is invariant to reparametrization.

Nonlinear regression analysis – Nonlinear regression models refer to models that are nonlinear in parameters. Nonlinear regression analysis mainly concerns the prediction of responses, statistical inferences of parameters estimates, and the goodness of fit of the nonlinear model.

Parameter-effects nonlinearity – Parameter-effects nonlinearity refers to a quantity which affects the rate of convergence of the estimates from Gauss–Newton method. It varies under different reparametrization.

Solution locus – The collection of points of regression function in the sample space evaluated at all feasible parameter values constitutes the solution locus. It is also known as expectation surface.

Introduction

Regression analysis refers to the statistical inferences for a model

$$y = f(x; \theta) + \epsilon \quad [1]$$

where $y \in \mathbb{R}$ is the response variable, $x = (x_1, \dots, x_k) \in \mathbb{R}^k$ are explanatory variables, and $\theta = (\theta_1, \dots, \theta_p) \in \mathbb{R}^p$ are

parameters. We name f the regression function, whose functional form is known up to some unknown parameters θ ; in addition, ϵ is an error term with zero mean and variance σ^2 . When the regression function f is linear in the parameters θ , it leads to the very popular and widely used statistical inferential techniques known as linear regression analysis. However, linear models are not always appropriate; therefore, one often needs to apply a nonlinear regression model, where f is nonlinear in θ . The statistical inferential problem concerning [1] is called a nonlinear regression analysis, when f is nonlinear in θ .

In the following sections, we present a set of topics in nonlinear regression. Among various estimation methods of nonlinear regression, the least-squares method is the most popular. The Gauss–Newton procedure is used to estimate the unknown parameters without calculating the Hessian matrix. Underlying the normality assumption of error terms, the maximum likelihood estimator is equivalent to the least-squares estimator.

In fields such as biochemistry, ecology, economics, and social sciences, there are plenty non-linear regression models being applied for a long time. Yet if the model needs to be scrutinized carefully, the quality of inferences from parameter estimates relies on the magnitude of model nonlinearity and parameter effects. We present a graphical example to illustrate this phenomenon.

Vectors and matrices are denoted, respectively, by bold-faced lower and upper case letters, such as $x \in \mathbb{R}^k$ and $X \in \mathbb{R}^{n \times k}$, and scalars are denoted by roman letters.

Estimation Methods

For a given data set $\{(x_i, y_i) : i = 1, \dots, n\}$ with size n , an empirical model based on the data can be written as

$$y = f(X; \theta) + \epsilon \quad [2]$$

where

$$X = \begin{bmatrix} x'_1 \\ \vdots \\ x'_n \end{bmatrix} = [x^{(1)} \dots x^{(k)}]$$

and

$$y = \begin{bmatrix} y_1 \\ \vdots \\ y_n \end{bmatrix}, \quad \epsilon = \begin{bmatrix} \epsilon_1 \\ \vdots \\ \epsilon_n \end{bmatrix}$$

In the data design matrix X , the i th row $\mathbf{x}_i' = (x_{i1}, x_{i2}, \dots, x_{in})'$ represents the i th observation, and the j th column $\mathbf{x}^{(j)} = (x_{1j}, x_{2j}, \dots, x_{nj})'$ represents the j th variable. We will use $f(\boldsymbol{\theta})$ to denote $f(X; \boldsymbol{\theta}) = (f(\mathbf{x}_1; \boldsymbol{\theta}), \dots, f(\mathbf{x}_n; \boldsymbol{\theta}))'$ for short. Let $\Theta \subset \mathbb{R}^p$ be the parameter space. The collection of points of regression function in the sample space evaluated at all feasible parameter values denoted by

$$f(\Theta) = \{f(\boldsymbol{\theta}) = f(X; \boldsymbol{\theta}) \in \mathbb{R}^n : \boldsymbol{\theta} \in \Theta \subset \mathbb{R}^p\}$$

is called the solution locus or expectation surface. A linear regression model has the solution locus as a p -dimensional hyperplane lying in the n -dimensional sample space. While a nonlinear regression model has the solution locus as a curved hypersurface in the sample space.

Least-Squares Estimation

The least-squares estimator of $\boldsymbol{\theta}$, denoted by $\hat{\boldsymbol{\theta}}$, is the point in the parameter space such that $f(\hat{\boldsymbol{\theta}})$ is closest to \mathbf{y} in the sample space among all feasible $f(\boldsymbol{\theta})$ in the solution locus. The least-squares estimator is derived from minimization of the residual sum of squares

$$S(\boldsymbol{\theta}) = \sum_{i=1}^n \{y_i - f(x_i; \boldsymbol{\theta})\}^2, \quad \boldsymbol{\theta} \in \Theta \subset \mathbb{R}^p \quad [3]$$

When f is differentiable with respect to $\boldsymbol{\theta}$, we solve for the least-squares solution $\hat{\boldsymbol{\theta}}$ in the following system of equations:

$$\left. \frac{\partial S(\boldsymbol{\theta})}{\partial \theta_\ell} \right|_{\boldsymbol{\theta}=\hat{\boldsymbol{\theta}}} = 0, \quad \ell = 1, \dots, p$$

The system of equations (called normal equations) are given by

$$\sum_{i=1}^n \frac{\partial f(x_i; \boldsymbol{\theta})}{\partial \theta_\ell} \{y_i - f(x_i; \boldsymbol{\theta})\} \Big|_{\boldsymbol{\theta}=\hat{\boldsymbol{\theta}}} = 0 \quad [4]$$

for $\ell = 1, \dots, p$. Or, in matrix form as

$$V(\hat{\boldsymbol{\theta}})' \hat{\boldsymbol{\epsilon}} = 0 \quad [5]$$

where $V_{i,\ell}(\boldsymbol{\theta}) = \partial f(x_i; \boldsymbol{\theta}) / \partial \theta_\ell$, and $\hat{\boldsymbol{\epsilon}} = \mathbf{y} - f(\hat{\boldsymbol{\theta}})$. The matrix $V(\boldsymbol{\theta})$, of size $n \times p$, is a velocity matrix with the ℓ th column denoting the instantaneous speed at $\boldsymbol{\theta}$ when moving on the solution locus along the ℓ th coordinate θ_ℓ . In a linear regression model, this velocity matrix is simply the data design matrix X and does not depend on the parameter values $\boldsymbol{\theta}$.

Often, normal equations do not have an analytic solution for $\boldsymbol{\theta}$ and numerical iterative procedures are needed. Below, we introduce the Gauss–Newton method for solving nonlinear least-squares problems based on iterative local linear approximations to the solution locus. Consider a small neighborhood of $\boldsymbol{\theta}^*$. The linear Taylor expansion is given by

$$f(x; \boldsymbol{\theta}) \approx f(x; \boldsymbol{\theta}^*) + \nabla_{\boldsymbol{\theta}} f(x; \boldsymbol{\theta}^*)' (\boldsymbol{\theta} - \boldsymbol{\theta}^*) \quad [6]$$

where

$$\nabla_{\boldsymbol{\theta}} f(x; \boldsymbol{\theta}^*)' = \left(\frac{\partial f(x; \boldsymbol{\theta}^*)}{\partial \theta_1}, \dots, \frac{\partial f(x; \boldsymbol{\theta}^*)}{\partial \theta_p} \right)$$

Therefore, the linear approximation to $f(x; \boldsymbol{\theta})$ around the neighborhood of $\boldsymbol{\theta}^*$ leads to an approximate residual sum of squares:

$$S(\boldsymbol{\theta}) \approx \sum_{i=1}^n \left\{ y_i - f(x_i; \boldsymbol{\theta}^*) - \sum_{\ell=1}^p V_{i,\ell}(\boldsymbol{\theta}^*) (\theta_\ell - \theta_\ell^*) \right\}^2$$

Using the linear Taylor expansion in the iterative update, the corresponding normal equations at the t th iteration are given by

$$V(\boldsymbol{\theta}_t)' V(\boldsymbol{\theta}_t) (\boldsymbol{\theta} - \boldsymbol{\theta}_t) = V(\boldsymbol{\theta}_t)' (\mathbf{y} - f(\boldsymbol{\theta}_t)) \quad [7]$$

The increment

$$\boldsymbol{\delta} = (V(\boldsymbol{\theta}_t)' V(\boldsymbol{\theta}_t))^{-1} V(\boldsymbol{\theta}_t)' (\mathbf{y} - f(\boldsymbol{\theta}_t))$$

serves as an update direction for next iteration. The Gauss–Newton method, an iterative approach, is then given by

$$\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t + \lambda_t \boldsymbol{\delta}_t$$

where λ_t is the step size. The update direction $\boldsymbol{\delta}$ is derived from the tangent plane approximation to the solution locus. This approximation is only valid in a local neighborhood of the current parameter estimator $\boldsymbol{\theta}_t$. The size of this neighborhood, where the linear approximation is valid, depends on the curvedness of the nonlinear model and its parametrization. It is possible that taking a full step, that is, $\lambda = 1$, will produce an increase in the residual sum of squares, especially when the Gauss–Newton update increment $\boldsymbol{\delta}$ has extended beyond the validity region of linear approximation. Thus, a smaller step size is required to ensure a decrease in residual sum of squares. Practically, λ_t can be taken as 1/2 step size of the previous step, that is, consecutively the step size 0.5, 0.25, 0.125, etc., till a decrease in residual sum of squares (Nocedal and Wright, 2006). Then, the procedure moves on to the next iteration. In addition, it is necessary to set up a requirement to stop the Gauss–Newton procedure. Equation [5] implies that the residual vector is orthogonal to the tangent plane of the solution locus, and can be used as stopping criterion for convergence. This concept leads to the relative offset orthogonality convergence criterion by Bates and Watts (1981).

The estimate of the asymptotic covariance of the least-squares estimate is given by

$$\text{Cov}(\hat{\boldsymbol{\theta}}) = \sigma^2 \left(V(\hat{\boldsymbol{\theta}})' V(\hat{\boldsymbol{\theta}}) \right)^{-1} \quad [8]$$

In a linear model, $V(\hat{\boldsymbol{\theta}}) = X$, and does not depend on the parameter estimates. Furthermore, the covariance expression [8] for a linear model does not require an asymptotic character, that is, it is valid regardless of the sample size.

Maximum Likelihood Estimation

Consider a normal distribution for the error term:

$$y - f(x; \boldsymbol{\theta}) = \epsilon \sim N(0, \sigma^2)$$

Then, the log-likelihood function is given by

$$\ell(\boldsymbol{\theta}, \sigma^2) = -\frac{n}{2} \log(2\pi) - \frac{n}{2} \log(\sigma^2) - \frac{S(\boldsymbol{\theta})}{2\sigma^2}$$

When σ^2 is known, maximizing the log-likelihood with respect to $\boldsymbol{\theta}$ is the same as minimizing the error sum of squares $S(\boldsymbol{\theta})$. Thus, the maximum likelihood estimator $\hat{\boldsymbol{\theta}}_{\text{mle}}$ is the same as the least-squares estimator $\hat{\boldsymbol{\theta}}$. On the other hand, when σ^2 is not known, $\partial \ell / \partial \sigma^2 = 0$ has the solution

$$\hat{\sigma}^2(\boldsymbol{\theta}) = \frac{S(\boldsymbol{\theta})}{n}$$

Substituting $\hat{\sigma}^2(\boldsymbol{\theta})$ into the log-likelihood expression results in

$$\ell(\boldsymbol{\theta}, \hat{\sigma}^2(\boldsymbol{\theta})) = \kappa - \frac{n}{2} \log(S(\boldsymbol{\theta}))$$

where κ is some constant. Maximizing $\ell(\boldsymbol{\theta}, \hat{\sigma}^2(\boldsymbol{\theta}))$ with respect to $\boldsymbol{\theta}_1$ we have

$$\hat{\boldsymbol{\theta}}_{\text{mle}} = \hat{\boldsymbol{\theta}} \quad \text{and} \quad \hat{\sigma}_{\text{mle}}^2 = \frac{S(\hat{\boldsymbol{\theta}})}{n}$$

In summary, when the noise structure follows a normal distribution, the maximum likelihood estimates equal the least-squares estimates.

Good Initials

For a linear model, the Gauss–Newton method will find the minimum in one single iteration from any initial parameter estimates. For a model which is close to being linear, the convergence for Gauss–Newton method will be rapid and not depend heavily on the initial parameter estimates. However, as the magnitude of model nonlinearity becomes more and more prominent, convergence will be slow or even may not occur, and the resulting parameter estimates may not be reliable. In that case, good initials are important.

One approach to find initial values is through transformation, so that the linear regression analysis under the assumption of additive error terms can be utilized (Bates and Watts, 1988; Ryan, 1997). For instance, the reciprocal of the Michaelis–Menten regression function

$$f(x; \boldsymbol{\theta}) = \frac{\theta_1 x}{\theta_2 + x} \quad [9]$$

leads to the model

$$y^{-1} = \frac{1}{\theta_1} + \frac{\theta_2}{\theta_1} \left(\frac{1}{x} \right) + \varepsilon$$

Indeed, this is a linear regression model denoted as

$$\tilde{y} = \beta_0 + \beta_1 \tilde{x} + \varepsilon$$

with $\tilde{y} = y^{-1}$, $\beta_0 = \theta_1^{-1}$, $\beta_1 = \theta_2 \theta_1^{-1}$, and $\tilde{x} = x^{-1}$. The least-squares estimates of β_1 and β_2 can therefore be transformed to provide initial values for the parameters in the Michaelis–Menten model. Alternatively, we can adopt a grid search, which evaluates the residual sum of squares at these parameter grid points and then finds the minimizing point among these grid points to provide initial values. In many occasions, the grid search helps to avoid improper initial values that lead to local, but not global, minimum of the residual sum of squares. Another alternative is to use uniform design points to replace the lattice grid points. Uniform design points are so designed to be as uniform and as space filling as possible and provide a more efficient search scheme (Fang *et al.*, 2000).

Assessing Nonlinearity

Given that the error terms are i.i.d. normally distributed random variables with zero mean, the least-squares estimator in linear models is unbiased, normally distributed and having minimum variance among all linear unbiased estimators (BLUEs) (i.i.d – independent and identically distributed). However, the least-squares estimator for nonlinear models does not have the same properties. The nonlinear least-squares estimator approaches BLUE only asymptotically. In addition, when the sample size increases, the Gauss–Newton iterative estimator becomes asymptotically numerically stable (Jennrich, 1969). However, if the model is highly curved and the first derivative $V(\boldsymbol{\theta})$ changes violently in the iteration, the least-squares estimator can be numerically unstable.

The parametrization is another important issue. Although the shape of the solution locus is fixed, the performance of Gauss–Newton interactive estimator varies with respect to different parameterizations. This depends on the nonlinearity in the model. There are two kinds of nonlinearity: intrinsic nonlinearity and parameter-effects nonlinearity (Bates and Watts, 1980; Hamilton *et al.*, 1982). The intrinsic nonlinearity is associated with the modeling and is invariant under reparametrization. The parameter-effects nonlinearity, however, can be lessened through a proper reparametrization. If either component of the nonlinearity is large, the least-squares estimate is hard to converge, or even does not converge. Furthermore, the asymptotic covariance of the least square estimate, given by $\sigma^2(V(\hat{\boldsymbol{\theta}})' V(\hat{\boldsymbol{\theta}}))^{-1}$, would change greatly in each step of the iteration, and the statistical inference based on the asymptotic normality becomes unreliable. In other words, the least-squares estimator in nonlinear regression depends on the curvedness of the underlying model and on the parametrization adopted.

Intrinsic Nonlinearity and Parameter Effects Nonlinearity

Of various measures for curvedness, the relative curvature array is widely used in nonlinear regression analysis and is presented below. The nonlinear least-squares fit is based on the iterative update of local linear approximations to the solution locus

$$f(x_i; \boldsymbol{\theta}) \approx f(x_i; \boldsymbol{\theta}^*) + \nabla_{\boldsymbol{\theta}} f(x_i; \boldsymbol{\theta}^*)' (\boldsymbol{\theta} - \boldsymbol{\theta}^*) \quad [10]$$

Consider a further extension to include the quadratic term in the Taylor expansion

$$f(x_i; \boldsymbol{\theta}) \approx f(x_i; \boldsymbol{\theta}^*) + \nabla_{\boldsymbol{\theta}} f(x_i; \boldsymbol{\theta}^*)' (\boldsymbol{\theta} - \boldsymbol{\theta}^*) + \frac{1}{2} (\boldsymbol{\theta} - \boldsymbol{\theta}^*)' \nabla_{\boldsymbol{\theta}}^2 f(x_i; \boldsymbol{\theta}^*) (\boldsymbol{\theta} - \boldsymbol{\theta}^*)$$

where $\nabla_{\boldsymbol{\theta}}^2 f(x_i; \boldsymbol{\theta}^*) = \partial^2 f(x_i; \boldsymbol{\theta}) / \partial \boldsymbol{\theta}^2$ is a $p \times p$ matrix of second derivatives for each $i = 1, \dots, n$. The magnitude of the quadratic term relative to the linear term determines the difference between the tangent plane [10] and the corresponding solution locus. Display $\nabla_{\boldsymbol{\theta}}^2 f(x_i; \boldsymbol{\theta}^*)$, $i = 1, \dots, n$, into a three-dimensional array $A(\boldsymbol{\theta}^*)$, which is of size $n \times p \times p$. This array $A(\boldsymbol{\theta}^*)$ is called the acceleration array at $\boldsymbol{\theta}^*$. The acceleration array A can be decomposed into two components, one parallel and the other normal to the tangent plane. The intrinsic nonlinearity is based on the normal component, and is invariant corresponding to any reparametrization. Factorization of the acceleration array into the tangent and normal components along with other technical details are placed in 'Appendix'.

In the linear regression model, the solution locus is a hyperplane. Uniform and equispaced grid lines on the p -dimensional parameter space also appear as uniform and equispaced grid lines on this hyperplane. In the nonlinear model, the tangent plane to the solution locus is used to serve as a local approximation to the locus. When these p -dimensional grid lines by $\boldsymbol{\theta}$ are mapped onto this tangent plane, we would prefer to see the resulting mappings as uniform and as equispaced as possible. The parameter-effects curvature measure [18] given in 'Appendix' can assess the deviation of the parameter curves from the uniform coordinate system. **Figure 1** presents plots of parameter curves using simulated data from Michaelis–Menten model.

Confidence Regions

In the iterative updates using local linear approximation, V plays the role as the design matrix X in the linear model. Under some suitable conditions on the error distribution and the regularity of the regression function f , the following holds asymptotically

$$\sqrt{n}(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}) \sim N(0, \sigma^2(V(\boldsymbol{\theta})' V(\boldsymbol{\theta})/n)^{-1}) \quad [11]$$

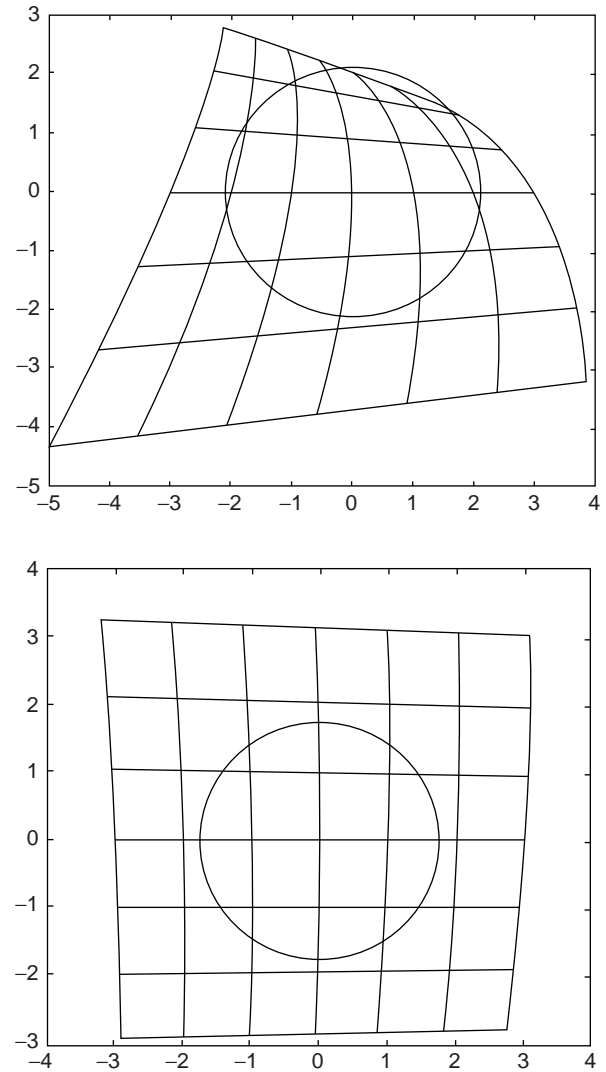

Figure 1 Parameter curves for the orthogonal parameters $\phi = R_{11}(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})$ using simulated data from the Michaelis–Menten model. The upper figure is with sample size $n = 10$; the lower figure is with sample size $n = 100$.

Using the linear approximation [10] and the asymptotic normality property [11], we can construct a confidence region and make statistical inferences, such as hypothesis testing, concerning $\boldsymbol{\theta}$. The performance of parameter confidence region and inferences depend on how well the linear approximation is, or in another aspect, on the curvedness of the solution locus at the point of least-squares estimate $\hat{\boldsymbol{\theta}}$.

Obtaining the observed information matrix at the convergence, that is, the information matrix evaluated at $\hat{\boldsymbol{\theta}}$, each diagonal element of the inverse of the information matrix provides a minimum variance bound for the corresponding parameter. An approximate $1 - \alpha$ joint confidence region for $\boldsymbol{\theta}$ is

$$(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})' V'(\hat{\boldsymbol{\theta}}) V(\hat{\boldsymbol{\theta}}) (\boldsymbol{\theta} - \hat{\boldsymbol{\theta}}) \leq \rho^2 F(p, n - p; \alpha)$$

or equivalently

$$\phi' \phi \leq \rho^2 F(p, n-p; \alpha)$$

where ϕ is a reparametrization [14] discussed in 'Appendix', and the boundary of this inference region is

$$\{\theta = \hat{\theta} + \rho \sqrt{F(p, n-p; \alpha)} R_{11}^{-1} u \text{ with } \|u\| = 1\}$$

Note that the degree of bias, nonnormality, and excessive variance depend on the model and data. For a given model with a fixed parametrization, data sample size helps to level off the curvedness. As the sample size increases, the sample space dimensionality increases. Consequently, the solution locus becomes flatter and flatter and gets closer to being linear in the higher dimensional sample space (Beale, 1960).

Coordinate System

The coordinate grids on the parameter space, named parameter curves, do not necessarily stay equispaced, straight, and parallel, when first lifted to the solution locus and then projected down to the tangent plane, especially when the locus is highly curved. When projecting the equispaced parameter curves in the parameter space onto the tangent plane, the degree of unequal spacing and the lack of parallelism of the mapped parameter curves lead to a measure of the parameter-effects nonlinearity.

The curvedness of a coordinate system will affect the quality of statistical inferences based on the asymptotic normality. When the mapped parameter curves onto the tangent plane are not uniform grid lines, the resulting confidence region may not be reliable. We use the well-known Michaelis–Menten model [9] to serve as an example for showing the parameter curves on the tangent plane. This model is commonly used for population dynamics in ecology studies, and for pharmacokinetics such as velocity of enzyme reaction. The parameter θ_1 indicates the maximal growth rate or maximal enzyme concentration level, and θ_2 is the half saturation coefficient or called Michaelis–Menten constant. Statistical inferences of these parameters help to understand the growth or increase pattern of a certain species.

The following simulation study illustrates that the parameter curves become more like grid lines in the Michaelis–Menten model, where $\sigma = 40$, $\theta_1 = 100$, $\theta_2 = 0.05$, and x 's come from the absolute values of $N(0, 2)$ random variables. We take two different sample sizes, $n = 10$ and $n = 100$. The mapped parameter curves displayed in **Figure 1** are colored in blue (ϕ_1) and black (ϕ_2). The circle in red prescribes an ideal 95% confidence region for a zero-curvature model and data. We can see in **Figure 1** that the ideal confidence region has gone beyond the square $[-3, 3]^2$ on the tangent plane when $n = 10$, while it stays inside the square for the case when $n = 100$. The radius of the circle is given by $\sqrt{F(2, n-2; 0.05)}$.

Diagnostics and Practical Considerations

The diagnostic study in nonlinear regression models is important for data analysis. The key factors are the nonlinearity of the model and the characteristics of data. After obtaining the least-squares estimates, some diagnostic checks of the magnitude of the intrinsic and parameter-effects nonlinearity are necessary to assess the performance of the estimates and the fitted model. In addition, some practical considerations are discussed.

- *Multicollinearity*: This occurs when some columns in the velocity matrix V are highly correlated and leads to ill-conditioned system of normal equations. It is an indication that the model may be overparametrized, and a simpler model, or a transformation of the regressors or parameters, may be considered. Sometimes, the degree of multicollinearity can be reduced by centering and scaling the regressors (explanatory variables) data (Bates and Watts, 1988).
- *Convergence status of the Gauss–Newton algorithm*: A slow speed of convergence or divergence of the Gauss–Newton algorithm serves as an indication that the model and data combination is not close to linear and the asymptotic normality property at the convergence point is not trustful.
- *Curvature measures at convergence and reparametrization*: Bates and Watts (1981) set bounds on the maximal values of intrinsic and parameter-effects nonlinearity measures in order to determine whether the estimator attains the global minimum of the residual sum of squares; furthermore, they offered a way to evaluate the parameter-effects array under a reparametrization (Bates and Watts, 1988). Nonetheless, little general guidance is provided to choose parameters attaining the minimum of parameter-effects curvatures.
- *Model adequacy*: Although R^2 is a common tool for model adequacy in linear regression analysis, it might be unreasonable to apply it in nonlinear models, as the number of parameters is not related to the number of explanatory variables. Alternatively, other lack-of-fit tests and residual plots are useful in the non-linear case.

Model Building

Model building aims at finding more realistic ways to describe the stochastic behavior observed in data. Models used in data analysis are approximations to the unknown regression function $f(x; \theta)$. It is desired to find nonlinear models that behave close to linear models in estimation and in inferences. In addition to the Michaelis–Menten model [9], we listed a few widely used models that have provided a great deal of useful applications of real data analysis in various scientific fields (Ratkowsky, 1983).

Yield-density model. The following three-parameter models are widely used for modeling relations between yield of a crop and the density of planting.

$$\begin{aligned} f(x; \theta) &= (\theta_1 + \theta_2 x)^{-1/\theta_3} \\ f(x; \theta) &= (\theta_1 + \theta_2 x + \theta_3 x^2)^{-1} \\ f(x; \theta) &= (\theta_1 + \theta_2 x^{\theta_3})^{-1} \end{aligned}$$

The analysis of growth data is important in many fields of study. The following models are practically used for modeling growth data:

1. Weibull model

$$f(x; \theta) = \theta_1 - \theta_2 \exp(-\theta_3 x^{\theta_4})$$

2. Logistic model

$$f(x; \theta) = \frac{\theta_1}{1 + \theta_2 \exp(-\theta_3 x)}$$

3. Richards growth model

$$f(x; \theta) = \frac{\theta_1}{(1 + \exp(\theta_2 - \theta_3 x))^{\theta_4}}$$

There are also other forms of parameterizations.

4. Monomolecular growth model

$$f(x; \theta) = \theta_1 (1 - \exp(-\theta_2 (x - \theta_3)))$$

If we reparameterize by replacing $-\theta_1 e^{\theta_2 \theta_3}$ with θ_2 and $e^{-\theta_2}$ by θ_3 , we have

$$f(x; \theta) = \theta_1 + \theta_2 \theta_3^x \quad (0 < \theta_3 < 1)$$

Some nonlinear regression models are constructed under theoretical consideration, for instance, the Michaelis–Menten model [9]. In physical and chemical fields, there are many models constructed from differential equations (Seber and Wild, 1989). The structural relationships between random variables and the realizations lead to different models; therefore, the assessment of models is very crucial. According to the principle of Occam's razor (Jaynes, 2003), simpler models are preferred than complicated models.

Further Reading

Multiresponse model. The models that we have discussed so far are for single response. When there are more than one response, and when the errors have a joint normal distribution, the least-squares method is still useful. If the normal assumption is not justified, the maximum likelihood or a Bayesian approach (Box and Tiao, 1992) are candidate alternatives.

Levenberg–Marquardt algorithm. The use of the Gauss–Newton algorithm with Levenberg–Marquardt

modifications (Marquardt, 1963) is to speed up the convergence as well as to stabilize the computation for near-singular $V'V$ in the least-squares normal equations. The Levenberg–Marquardt modifications are a compromise between the Gauss–Newton method and the steepest descent method.

Differential geometric view. The measures of curvature described above are based on the geometric properties of the solution locus $f(\theta)$ relative to the parametrization θ . Therefore, a different approach to assessing the degree of nonlinearity is through studying the geometric structures of the distributions. When a normal error assumption is assumed, we are imposing a Euclidean metric on the underlying class of distributions. Changing the error distribution leads to a different metric, thus changing the geometry and concepts of curvature. The study of probability and information by way of differential geometry is known as information geometry. We refer the reader to the work by Amari (1982) and by Amari and Nagaoka (2000) for detailed accounts of differential geometric viewpoints and approaches.

Generalized linear model. The generalized linear models (GLMs) extend the linear regression to include the response variables that are no longer normally distributed, such as binary or count data. If the distribution of response variables belongs to the exponential family, a link function can be applied on the expectation of y to connect to the linear predictors $X\theta$. This makes the expectation surface nonlinear. However, the expectation surface is determined by quantities linear in parameters with a predetermined nonlinear link function. It is thus easier to perform statistical inference under GLMs. Many commercial softwares have been developed for estimation.

Semiparametric and nonparametric regression. If the aim of data analysis is to obtain a good fit to the response curve on the explanatory variables, a nonparametric regression (also known as curve fitting) is probably a better alternative than a nonlinear regression model. The latter is a parametric approach, and its aim is to explore and predict the response at given values of explanatory variables as well as to make statistical inferences based upon interpretation of parameter estimates. The semiparametric regression, which adopts a model that has parametric and nonparametric components, is another alternative to non-linear regression modelling.

Appendix

Factorization of D and A

Due to the symmetric structure of the second derivatives, that is $\partial^2 f(\theta^*) / \partial \theta_\ell \partial \theta_\ell = \partial^2 f(\theta^*) / \partial \theta_\ell \partial \theta_\ell$, there are $p(p-1)/2$ redundant columns in A . Remove these redundant columns, and denote such a resulting matrix by W , which is of size $n \times p(p+1)/2$. Let $D = [V \ W]$, whose

columns are formed by velocity and acceleration vectors. QR-factorize the matrix D as

$$D = \left[\begin{array}{c|c} n \times p & n \times p' \\ \hline \mathbf{Q}_T & \mathbf{Q}_N \end{array} \right] \left[\begin{array}{c} R \\ - \\ 0 \end{array} \right]$$

with

$$R_{(p+p') \times (p+p')} = \begin{bmatrix} p \times p & p \times p' \\ p' \times p & p' \times p' \\ 0 & R_{22} \end{bmatrix}$$

where \mathbf{Q}_T consists of p orthonormal n -vectors and spans the tangent space of the solution locus at θ^* , \mathbf{Q}_N consists of $p' = p(p+1)/2 - p$ orthonormal n -vectors, which are normal to \mathbf{Q}_T and together with \mathbf{Q}_T have the same column span as \mathbf{W} , and \mathbf{R} is a $(p+p')$ square matrix with zero entries in the lower-triangular part. The \mathbf{Q}_0 matrix is composed of the remaining orthonormal column basis. These columns are orthogonal to D and, together with \mathbf{Q}_T and \mathbf{Q}_N , they form a complete orthonormal basis for \mathbb{R}^n . Note that \mathbf{Q}_0 has no contribution to either the intrinsic nor the parameter-effects non-linearity. In fact, we can write an economic QR-factorization:

$$D = [\mathbf{Q}_T \ \mathbf{Q}_N] R \quad \text{with} \quad R = \begin{bmatrix} R_{11} & R_{12} \\ 0 & R_{22} \end{bmatrix}$$

Note that all the above-mentioned matrices and arrays depend implicitly on θ^* , the current update of the least-squares estimate. We omit θ^* from all these matrices and arrays for notation simplicity when there is no ambiguity.

In the classical geometry, the curvature corresponding to a direction is the ratio of the length of the second derivative to the squared length of the first derivative. In the context of residual sum of squares $S(\theta)$, such a curvature measure combines the first derivatives and the second derivatives in such a way that the nonlinearity due to model and due to parametrization are mixed together. This curvature measure can be decomposed into two components: the intrinsic and the parameter-effects nonlinearity. The second derivative array A can be decomposed accordingly into two components reflecting the model effects and the parameter effects. By left multiplying \mathbf{Q}_T' and \mathbf{Q}_N' to A , we have $A_T = \mathbf{Q}_T' A$ and $A_N = \mathbf{Q}_N' A$ representing, respectively, the component parallel and normal to the tangent plane. Consider a line in the parameter space Θ and its corresponding trajectory along the direction b , or called lifted line, on the solution locus:

$$\text{line in } \Theta : \theta(t) = \theta^* + tb, \text{ lifted line : } f(\theta^* + tb)$$

The second derivative of the lifted line with respect to parameters along the direction b is given by $b' \odot [\mathbf{Q}_T \ \mathbf{Q}_N]' A \odot b$ with decomposition:

$$\overbrace{b' \odot A_T \odot b}^{p \times 1} \oplus \overbrace{b' \odot A_N \odot b}^{p' \times 1},$$

where the direct sum is not a matrix sum but rather is used to denote two components and \odot denotes the slicewise multiplication. For instance, A_N is a $p' \times p \times p$ array with the i th slice a $p \times p$ matrix consisting of entries $A_{N,ijk}$, $j, k = 1, \dots, p$. When the p -vector b and its transpose are right and left multiplied to each slice of A_N , it gives a scalar for each slice. Collectively, $b' \odot A_N \odot b$ forms a p' -vector.

Intrinsic Nonlinearity

The intrinsic curvature corresponding to the direction b at θ^* is given by

$$\frac{\|b' \odot A_N(\theta^*) \odot b\|}{\|V(\theta^*)b\|^2} \quad [12]$$

This quantity is invariant under any reparametrization. Often, we consider a scaled curvature instead:

$$\kappa_b^N = \rho \frac{\|b' \odot A_N(\theta^*) \odot b\|}{\|V(\theta^*)b\|^2} \quad [13]$$

where $\rho = s\sqrt{p}$ with $s^2 = S(\theta^*)/(n-p)$. The quantity ρ is called the standard radius so that $\rho\sqrt{F_{p,n-p;\alpha}}$ is the radius for the $100(1-\alpha)\%$ confidence sphere of a reparametrization ϕ in a neighborhood of θ^* :

$$\phi = R_{11}(\theta - \theta^*) \quad [14]$$

With such a reparametrization, the velocity matrix $\nabla_\phi f(X; \phi)$ will have orthonormal columns, and the second derivative array projected onto the space spanned by \mathbf{Q}_T and \mathbf{Q}_N will become

$$(\mathbf{R}_{11}^{-1})' \odot [\mathbf{Q}_T \ \mathbf{Q}_N]' A \odot \mathbf{R}_{11}^{-1}$$

Then, we have the definition of the relative curvature array as follows:

$$C = \rho (\mathbf{R}_{11}^{-1})' \odot [\mathbf{Q}_T \ \mathbf{Q}_N]' A \odot \mathbf{R}_{11}^{-1}$$

Note that C is a scaled second derivative array with parametrization ϕ [14] and is of the same size as $[\mathbf{Q}_T \ \mathbf{Q}_N]' A$, which is a $(p+p') \times p \times p$ array. Its corresponding decomposition is given by $C = C_T \oplus C_N$ with

$$C_T = \overbrace{\rho (\mathbf{R}_{11}^{-1})' \odot A_T \odot \mathbf{R}_{11}^{-1}}^{p \times p \times p} \quad [15]$$

and

$$C_N = \overbrace{\rho (\mathbf{R}_{11}^{-1})' \odot A_N \odot \mathbf{R}_{11}^{-1}}^{p' \times p \times p} \quad [16]$$

The intrinsic curvature measure can then be expressed as

$$\kappa_d^N = \|d' \odot C_N \odot d\| \quad [17]$$

where d has unit length and the corresponding direction in θ coordinates is $b = \mathbf{R}_{11}^{-1} d$. We can use a maximal value $\max_d \kappa_d^N$ or an average quantity $\int \kappa_d^N$ to account for the intrinsic curvature measure.

Parameter-Effects Nonlinearity

To assess the deviation of parameter curves from the uniform coordinate system, the parameter-effect curvature measure is introduced below

$$\kappa_d^T = \|d' \odot C_T \odot d\| \quad [18]$$

The parameter-effects curvature is the projection of the second derivative array of the solution locus onto the tangent plane, where the derivatives are taken over the parameters of interest. The parameter-effects curvature [15] and the intrinsic curvature [16] are collectively called the relative curvature array. Unlike the invariance of intrinsic curvatures, the parameter-effects curvatures change when a different reparametrization is carried out in the nonlinear model.

Glossary

Nonparametric statistical methods – The statistical methods that do not assume a particular distribution, such as the normal, from which the data are sampled.

Introduction

Nonparametric statistical methods are used in situations in which it is unreasonable to assume that the sample was drawn from a population distribution with a particular parametric shape, such as the normal distribution. For example, when the sample size is small and the distribution of the observations is skewed, statistical methods based on the assumption of a normal distribution may be inappropriate. Nonparametric statistical methods do not have *a priori* assumptions about the population distribution and, therefore, are sometimes referred to as distribution-free methods.

Nonparametric methods have several properties that are worth mentioning. First, they are suitable for categorical data, which are common in educational research. Categorical variables have either nominal or ordinal measurement level, but may also represent counts of particular events. Examples of nominal variables include the kinds of arithmetic errors made by students, and the assignment of each student to one of three remedial teaching methods of interest. In statistical analysis, such groups may be identified by means of numbers 1, 2, and 3, which only serve to distinguish them. An example of an ordinal variable is the teacher's rank ordering of students with respect to perceived need of remedial teaching. An example of a count is the frequency of students in each remedial teaching program who receive help.

Nonparametric methods may also be in order for interval-level variables, such as students' motivation, for which the population distribution is unknown. The consequence of using nonparametric methods is that the test scores are treated as ordinal rather than interval variables. By doing this, information is lost about the distances between scores and the power of statistical tests is reduced. Researchers often consider this unacceptable, and analyze

their data as if the sampled scores on a variable stem from a known distribution.

Second, nonparametric methods are appreciated for their weak assumptions. Thus, instead of assuming distributions such as the normal, exact distributions are derived for particular statistics of interest. For example, a nominal variable may follow a multinomial distribution of which the category probabilities are estimated from the data. Other assumptions may be relaxed or completely dropped. For example, instead of assuming a linear relationship between numerical variables as in linear regression, relationships may be estimated from the data, as in kernel smoothing (Fox, 2000a; Ramsay and Silverman, 1997). Weak statistical models are important because they do not make assumptions beyond the level of knowledge expressed in many theories in educational and other social and behavioral sciences.

Third, it is sometimes said that nonparametric statistical models are convenient because they are easy to use. Some restraint may be in order here, because nonparametric methods are often based on complex mathematical considerations that may not be as easy to grasp as those underlying parametric methods. For example, several nonparametric methods are based on combinatorial math, which is notorious for running into badly manageable computations as sample size increases or the numbers of variables increases, and all possible patterns of scores have to be taken into account.

Fourth, the results of nonparametric statistical methods are sometimes not much different from those obtained by means of parametric methods that have been applied even when the assumptions on which they are based were violated. Thus, sometimes parametric statistical methods are robust against the violation of the normality assumption and the use of nonparametric counterparts, which may be more appropriate from a mathematical point of view, becomes less salient. This is true, for example, for the parametric Student's *t*-test. However, for other methods, such as regression analysis, it has been shown repeatedly that the estimation of a relationship from the data may lead to different and interesting results that would have been obscured when a particular parametric function, such as the linear or the logistic, had been fitted. Thus, there is room for nonparametric statistical methods, which are also illustrated by some examples provided in the article.

Examples of Nonparametric Statistical Methods

The goal of statistical analysis is to estimate properties of interest from the data, such as the distribution of a variable or the difference between groups with respect to the means on a variable, and to test hypotheses about interesting research questions. First, we review a few well-known nonparametric statistical tests from the myriad of test procedures (e.g., Siegel, 1956; Siegel and Castellan, 1988; Wasserman, 2004, 2006) based on known, exact sampling distributions, and then we discuss methods for obtaining sampling distributions and probabilities of exceedence when exact sampling distributions are unknown.

Estimating Distributions and Drawing Inferences

An important step in data analysis is to inspect the distribution of the observations. Rather than assuming a normal distribution and estimating the mean and variance, one can also estimate the complete distribution from the data. An example of a nonparametric method is the simple histogram that estimates the population distribution directly from the data (**Figure 1**). As the sample has a limited number of observations, the histogram is discrete and jagged. Thus, sometimes it may be convenient to smooth the histogram. Kernel smoothing produces the result shown by the solid curve in **Figure 1**. Smoothing has the effect of bringing out the salient features of the distribution at the expense of irregularities that probably are due to sampling error. For example, the solid smooth

Figure 1 Example of an estimated distribution of sum scores (e.g., the number-correct score on an educational test) by means of a histogram, kernel smoothing (solid curve), and a normal approximation (dashed curve).

curve suggests that the distribution is skewed to the left and that the frequency of score 12 may be too large due to sampling error.

The smooth dashed curve in **Figure 1** shows the normal approximation to the histogram. A glance at the graph shows that the normal seems to overestimate the lower-score frequencies and underestimate the higher-score frequencies. The Shapiro–Wilk test, which is a well-known nonparametric test for evaluating whether the observations deviate from the normal curve, yields a value equal to 0.894 ($P < 0.000$); thus, the hypothesis of normality is rejected. The Kolmogorov–Smirnov test is a more general, often-used nonparametric method that can be used to test whether the data come from a hypothesized distribution, such as the normal. Often, it has less power than the Shapiro–Wilk test to detect violations of normality, but for the data in **Figure 1** the value of the test statistic is 0.183 ($P < 0.000$). Again, normality is rejected. Neither test makes assumptions about the population distribution of the data.

Researchers may wish to know whether the distributions of an outcome variable are the same across groups, for example, as in a control-group study on the effect of a teaching program. When the variable is ordinal, it does not make sense to assume that it follows a normal distribution and compare the means using a parametric t -test. Such a test is also inappropriate when an interval variable does not have a normal distribution. Alternatively, the nonparametric Mann–Whitney U test, also known as the Wilcoxon rank-sum test, is a good candidate for testing the null hypothesis that two independent samples come from the same population against the alternative that the samples come from two different population distributions which are identical in shape but different in location.

The Mann–Whitney U test is based on the common rank ordering according to ascending magnitude of all observations from two samples, say A with size N_1 and B with size N_2 , and counts for each observation from B by how many observations from A it is preceded; test statistic U equals the sum of these counts (for simplicity, we ignore the possibility of ties). When the two distributions are completely separated, each observation from A either precedes each observation from B , which results in maximum $U = N_1 N_2$, or is preceded by each observation from B , which results in minimum $U = 0$. Thus, high and low values of U indicate different distributions, and intermediate values indicate largely overlapping distributions. For small sample sizes (i.e., the size of the larger sample does not exceed 20), the probabilities of exceedence can be read from tables especially prepared for this purpose. When the larger sample exceeds size 20, U has been shown to approach a normal distribution with

$$\mu_U = \frac{N_1 N_2}{2}, \text{ and } \sigma_U = \sqrt{\frac{N_1 N_2 (N_1 + N_2 + 1)}{12}}.$$

The standard normal statistic $z = (U - \mu_U)/\sigma_U$ may be used to test the null hypothesis using probabilities from tables for the normal distribution. Several other tests for testing differences in location exist for a variety of research designs, such as the Wilcoxon signed rank test for paired samples, and the Kruskal–Wallis test for comparing differences in location between k ($k \geq 3$) independent samples.

Determining Degree of Association

Suppose, two numerical variables X and Y have been sampled from the same population and one wishes to know the degree to which they are linearly related. An extremely well-known statistic for this purpose is Spearman's product-moment correlation, denoted ρ in the population and r in the sample. Assuming bivariate normality for X and Y and a sample of size N , the null hypothesis that $\rho = 0$ can be tested using a t statistic, which can be shown to depend only on r and N .

Again, what if variables X and Y are ordinal or one is reluctant to assume bivariate normality? An alternative to the product-moment correlation is Spearman's rank correlation r_s . Here, the scores on both variables are replaced by the corresponding ranks, which for brevity we also denote X and Y . For example, for a respondent indexed i , the pair of ranks ($X_i = 7, Y_i = 15$) show that (s)he was ranked 7 on variable X and 15 on variable Y . The difference between paired ranks equals $d_i = 7 - 15$, and so on for other respondents. Tied scores are replaced by the average of the ranks assigned, had no ties been observed. The product-moment correlation between the two rankings X and Y provide the values of r_s . Ignoring ties for simplicity, and using differences d between paired ranks, r_s equals

$$r_s = 1 - \frac{6 \sum d_i^2}{N(N^2 - 1)}.$$

For small samples, the null hypothesis that $\rho_s = 0$ can be evaluated by considering all possible rank orderings or permutations of Y given a particular rank ordering of X , and determining the value of r_s for each pair of ranks X and Y . As under the null hypothesis, each permutation of Y has the same probability, $(N!)^{-1}$, the probability of a particular value for r_s simply is a multiple of $(N!)^{-1}$, and a table based on the distribution of r_s given N is readily prepared. This table can be used for hypothesis testing. For, say, $N \leq 30$, this is feasible but for larger N one runs into combinatorial problems. For $N \geq 10$ (Hays, 1981: 598), a t -test may be used for testing the null hypothesis. Other coefficients exist for expressing degree of association, such as Kendall's τ_b , which corrects for tied observations (Liebetrau, 1983: 51–53).

When X and Y are nominal, a two-way contingency table is set up with cells for all combinations (x, y) and

frequency counts in each cell, which reflect how often a particular combination is observed in the sample. The null hypothesis of no association may be tested using a chi-squared statistic. The strength of the association may be expressed by several coefficients, for example, the phi-coefficient when both X and Y have two categories, and Cramér's V when the number of categories is greater and not necessarily equal for X and Y (Liebetrau, 1983).

Bootstrap and Permutation Tests

When the population distribution of the observations is unknown, it may happen that the sampling distribution of a statistic of interest, say T , derived from the data also is unknown. In this case, a computer-intensive way of approximating the sampling distribution of T is to draw a large number of samples of size N with replacement from the sample, and then compute statistic T for each so-called bootstrap sample. The distribution of T across the bootstrap samples can be used to determine a confidence interval for parameter τ of which T is the estimate, for example, by identifying the 2.5th and the 97.5th percentile and using these as lower and upper bounds, respectively. This procedure is known as the nonparametric bootstrap (Efron and Tibshirani, 1993). Statistic T can be any quantity of interest, such as the median or the range of a distribution, a difference between group medians, or an association measure between scores.

An example of a related procedure is known as the permutation test (also, see the discussion of the test of the null hypothesis that Spearman's $\rho_s = 0$). In general, for null hypothesis $\tau = 0$, the statistic T is determined for all possible arrangements of the sampled data, which are also known as permutations. The distribution of T across these permutations is the sampling distribution of T under the null hypothesis. If one wishes testing the null hypothesis $\tau = 0$ at the 5% level against the alternative that $\tau > 0$, then the 95th percentile of the sampling distribution defines T_{crit} . If the observed value of T in the original sample, denoted T_{obs} , exceeds T_{crit} , the null hypothesis is rejected. The number of possible permutations can become excessively large, even for high-powered computers, and then a large random sample of permutations may be used instead. For some statistics T , the distribution of T approaches a known distribution in larger samples, as with Spearman's r_s , which approaches a Student's t -distribution.

Specific Nonparametric Methods: Nonparametric Regression

As regression analysis is regularly used in educational research, this section presents nonparametric regression analyses as an illustration of a more advanced nonparametric

statistical method. First, the parametric multiple regression analysis is discussed. This method relates a response variable, denoted Y , linearly to one or more explanatory variables, denoted $X_j (j = 1, \dots, m)$, such that

$$Y = \alpha + \sum \beta_j X_j + \varepsilon.$$

In the regression equation, the regression intercept is denoted by α , the regression coefficients by $\beta_j (j = 1, \dots, m)$, and the residual error by ε , which is assumed to have 0 mean for fixed values of the explanatory variables. The regression parameters are estimated fitting the regression equation to the data of N observations (indexed by i) so as to minimize $\sum \varepsilon_i^2$. Hypotheses of interest are whether $\beta_j = 0 (j = 1, \dots, m)$ against a one-sided or a two-sided alternative, and whether the amount of variance explained by the model, denoted R^2 , equals 0 (i.e., $R^2 = 0$), against the alternative that it is positive. For testing these hypotheses, it is assumed (among others) that the conditional distribution of Y is normal, with mean $\alpha + \sum \beta_j X_j$ and constant variance σ^2 . This amounts to assuming that $\varepsilon \sim N(0, \sigma^2)$.

An Overview of Nonparametric Regression Methods

Suppose, the researcher has insufficient evidence to support linearity, normality, and equal variance, or his/her substantive theory does not imply this degree of structure. Then, (s)he could try nonparametric regression methods to study the relationships between variables. We illustrate that the exact shape as estimated directly from the data may provide interesting information about relationships.

For simplicity, we consider only models with one explanatory variable, X (see Fox, 1997, 2000b, for many generalizations). Then, when one expects Y and X not to be linearly related, the simplest option is to compute the mean \bar{Y} conditional on separate values of X , and take the mean as the regression estimate; that is, $\hat{Y}|x = \bar{Y}|x$ is computed and a graph is drawn that connects adjacent conditional estimates $\hat{Y}|x$. Problems may arise when X is continuous and many different values are observed so that only few values of Y are tied to one value of X , when the number of different values of X is manageable but the total sample size is relatively small, which leads to the same problem, or when the combination of both occurs.

The problem of too few observations per value of X may be accommodated by the use of so-called bins. Order all observations according to X from small to large, and define a subset of smallest adjacent X values to form the first bin, then a subset of the next adjacent values of X to form the second bin, and so on. Bins are indexed $k = 1, \dots, K$. Then, \bar{Y} is computed based on all observations in the k th bin ($k = 1, \dots, K$). The resulting values $\hat{Y}|\text{bin}(k)$ are plotted in a graph, which often appears jagged. Important decisions in binning concern the

width of a bin and the minimum number of observations in a bin. These decisions affect both the bias and the variance of the estimate of mean Y , and smaller bias often implies greater variance and vice versa.

Bins may also be defined as overlapping windows, where each next window has moved further to the right across the scale of X , so that values of X enter the window from the right and exit the window from the left. As for bins, windows may have either a fixed width defined by values of X or they contain a fixed number of $n + 1$ observations. In local averaging, for each window \bar{Y} is computed on the basis of all the observations on X that are in the window. When the number of observed values on X is small, the resulting graph is jagged, as with binning. Windows that contain a fixed number of $n + 1$ observations can be moved across all N observations on X after these observations have been ordered from small to large, such that each observation can be the central focal value x_0 of a window once. The other observations in the window can be defined to be the n nearest neighbors of x_0 . Then, N conditional estimates $\hat{Y}|x_0$ (the conditioning is on x_0 plus its n nearest neighbors) lead to a relatively smooth curve. As with binning, either the width of the window or the size of n must be determined. Another problem is that with fixed n , x values near the endpoints have more-similar neighborhoods than other x values, so that the regression curve tends to flatten near the endpoints.

Kernel smoothing takes local averaging a step further by differentially weighing the y values corresponding to neighbors of focal point x_0 , such that y values of neighbors close to x_0 receive more weight than y values of neighbors further away in the window. Denoting weights by w_i the local average is obtained by means of

$$\hat{Y}|x_0 = \frac{\sum_{i=1}^N w_i y_i}{\sum_{i=1}^N w_i}.$$

Weight w_i is the kernel function, defined as $w_i = K[(x_i - x_0)/b]$ (b is explained shortly). Several choices are possible but a convenient choice is the Gaussian kernel,

$$w_i = K\left(\frac{x_i - x_0}{b}\right) = \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}(x_i - x_0/b)^2},$$

in which b is called the bandwidth. Small bandwidth values produce jittery curves showing too much random detail (too much variance) and large values produce smooth curves that erase salient features of the regression (too much bias). Thus, finding a value of b that counterbalances bias and precision is an important topic.

The data within a window may be distributed approximately equally dense but they may also pile up on one side of the window. In the latter case, estimate $\hat{Y}|x_0$ may be heavily biased. Local polynomial regression provides a

better estimate by fitting a polynomial regression model to the data in the window,

$$Y = \alpha + \beta_1(X - x_0) + \beta_2(X - x_0)^2 + \cdots + \beta_p(X - x_0)^p + \varepsilon,$$

using weighted least squares, such that $\sum_{i=1}^n w_i^2 \varepsilon_i^2$ is minimized so as to obtain estimated regression parameters. Then, for this window $\hat{Y}|x_0 = \hat{\alpha}$ is the point on the regression curve, and an estimated curve is obtained as the window moves along. As for higher p , multicollinearity sets in, $p = 1, 2$, and 3 are convenient practical choices.

With spline regression (Marsh and Cormier, 2002; Ramsay and Silverman, 1997), we return to binning but instead of taking an unweighted average we now fit a polynomial regression model,

$$Y = \alpha + \beta_1 X + \beta_2 X^2 + \cdots + \beta_p X^p + \varepsilon,$$

to the data in the bin such that the regression curves in adjacent bins connect smoothly to constitute one smooth curve across the bins. Not only should curves from adjacent bins connect the points on the boundaries of the bins, also called knots, but in passing a knot, the slope of the curve should not change abruptly, meaning that the first derivative is smooth at the knot, and the curvature of the curve, for example, should not to change abruptly from smooth to rough, meaning that the second derivative also is smooth at the knot. This requires a polynomial to have at least degree $p = 3$, because linear spline functions ($p = 1$) only connect straight lines between bins, and quadratic spline functions ($p = 2$) in addition only guarantee a smooth change of the slope but do not prevent sudden breaks in this change. See Green and Silverman (1994) for methods that control the balance between bias and variance and prevent curves from becoming jumpy.

Both local polynomial regression and spline regression are extremely flexible and overcome many of the weaknesses of other nonparametric regression methods, such as the flattening of curves near the endpoints. Both methods use parametric functions to adequately describe interesting features of relationships but not to hypothesize that relationships are naturally linear, quadratic, and so on. Inference with respect to nonparametric regression is based on estimated confidence bands around the regression curve. Several possibilities exist, the nonparametric bootstrap being one of them. In addition, nested models may be tested against one another.

An Application of Kernel Smoothing to Educational Test Data

Nonparametric regression methods find their application, for example, in a large and important class of models for educational measurement, known as item response models, discussed elsewhere in this encyclopedia. These models use the scores (binary, nominal, and

ordered) of a large sample of students (often, $N \gg 500$) on several items that measure the same ability, for constructing an ability scale on which students can be located. Each item may present, for example, an arithmetic problem to the student and the scores on each of the items may be driven by a student's ability to perform well on such problems.

The key feature of item response models is the nonlinear regression of each separate item score on the ability. Let the random variable for an item score be denoted X_j . It is further assumed that the ability is represented by a latent variable, denoted by θ , the scores on which are inferred from the student's observed item scores through the estimation of the item response model. For $X_j = 0, 1$ (e.g., incorrect/correct solutions), a typical example of a regression function is the 2-parameter logistic function (e.g., Van der Linden and Hambleton, 1997),

$$P(X_j = 1|\theta) = \frac{e^{a_j(\theta - b_j)}}{1 + e^{a_j(\theta - b_j)}};$$

see **Figure 2** for the graphical representation of two logistic functions. Parameter b_j gives the value of θ for which the probability of a correct solution equals 0.5, and parameter a_j is monotonically related to the function's steepest slope, which is in the inflexion point $(b_j, 0.5)$. For parameter estimation, marginal maximum likelihood (MML) may be used, which assumes that θ is normal when the item parameters are estimated, and then assumes that the estimated item parameters are fixed when for each individual an ability score θ is estimated.

An important question is whether a 2-parameter logistic regression function and a normal θ are not unduly restrictive for the problem of interest (Junker and Sijtsma, 2001).

Figure 2 Two 2-parameter logistic functions: solid curve has parameters $b_j = -0.25$ and $a_j = 2$, and dashed curve has parameters $b_j = 0.25$ and $a_j = 1.0$.

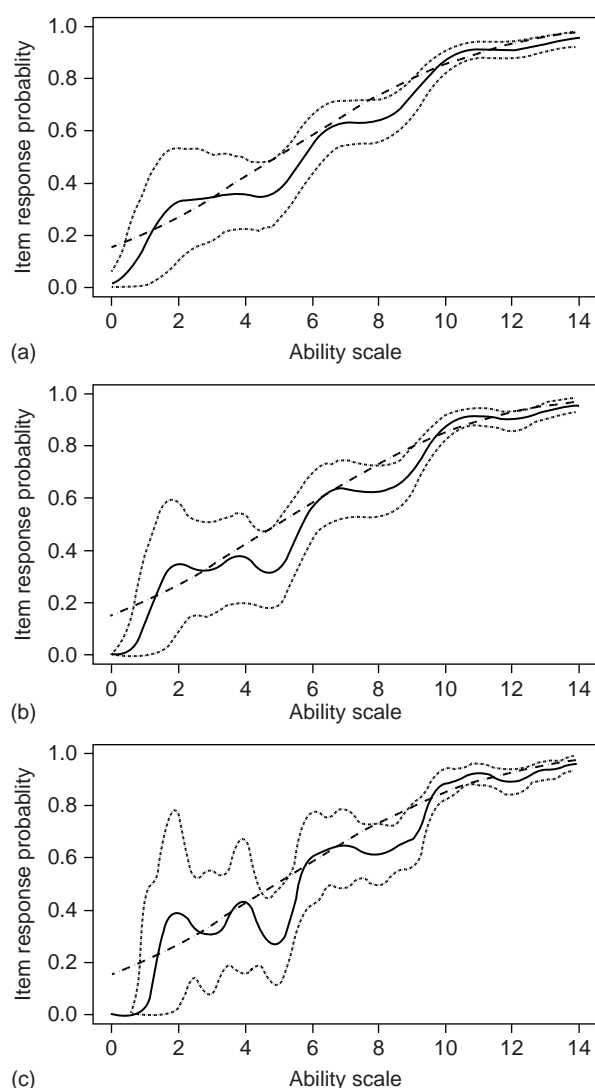

Figure 3 Estimated item response functions (solid curves) with 95% confidence envelopes (dotted curves): bandwidth parameters (a) $h = 2$; (b) $h = 1.5$, and (c) $h = 1.0$. The dashed curve in each figure is the estimated 2-parameter logistic function.

Indeed, in the context of item response theory, binning, kernel smoothing, and spline regression each have been proposed and used as alternatives for logistic and other parametric functions. **Figure 3** shows the estimated kernel regression functions of an item response function from a 15-item arithmetic test, for three levels of the bandwidth parameter: $h = 2$ (**Figure 3(a)**), $h = 1.5$ (**Figure 3(b)**), and $h = 1$ (**Figure 3(c)**). The dashed curve is a 2-parameter logistic curve based on MML estimates of the two item parameters, a_j and b_j . The solid curve is the estimate based on kernel smoothing, and the dotted curves are the 90% confidence envelopes. As h becomes smaller, the regression curve becomes jumpier. Each nonparametric estimate suggests that the logistic estimate often seems

to overestimate the true-response probabilities, and does not adequately capture the slope of the regression function at different ranges of the ability scale.

The results illustrate the usefulness of nonparametric data analysis for revealing systematic trends in the data that might have gone unnoticed had parametric methods been used. For example, the nonparametric regression estimate shows that the item does not discriminate well in the ability range from score 2 to score 5 whereas the slope parameter of the parametric regression function cannot reveal this kind of detail. Thus, the nonparametric estimate provided a more realistic impression of how the item functions for measuring ability differences between students.

Further Reading

Introductory textbooks on nonparametric statistics are, for example, Hollander and Wolfe (1999), Sheskin (2007), and Siegel (1956; Siegel and Castellan, 1988). An example of a multivariate nonparametric method that may be of special interest for educational researchers is the nonparametric approach to multiple analysis of variance (MANOVA) (Puri and Sen, 1971) to test group differences on multiple outcomes (e.g., several cognitive skills). Finch (2005) showed that the nonparametric MANOVA has good statistical properties in situations in which, for example, the normality assumptions underlying the parametric MANOVA are violated. Another example includes the work by Linting *et al.* (2007), who discuss nonlinear principal components analysis based on the monotone transformation of ordinal variables such that the relationship with other variables is optimized. For nonparametric regression techniques, the availability of high-speed computers has led to a rapid development of computer-intensive methods, such as bootstrapping and resampling, linear and nonlinear smoothing, and graphical methods, which can handle complex multivariate data (e.g., Akritas and Politis, 2003; Wasserman, 2006).

Glossary

Propensity score – The conditional probability of treatment given observed covariates.

Sensitivity analysis – An analysis that shows how relaxing an assumption might alter a conclusion.

Introduction

Definition

William G. Cochran (1965) defined an observational study as a comparison of treated and control groups in which:

the objective is to elucidate cause-and-effect relationships [... in which it] is not feasible to use controlled experimentation, in the sense of being able to impose the procedures or treatments whose effects it is desired to discover, or to assign subjects at random to different procedures.

Treatments, policies, and interventions that are expected to benefit recipients can be studied in experiments that randomly allocate experimental subjects to treatment groups; therefore, comparable subjects receive competing treatments (Boruch, 1997). Observational studies are common, nonetheless, in most fields that study the effects of treatments on people, because harmful or unwanted treatments cannot be imposed on human subjects. When treatments are not randomized, subjects assigned to competing treatments may not be comparable; therefore, differences in outcomes may or may not be effects caused by the treatments (Rubin, 1974).

Examples

Two examples of observational studies are described. Later sections refer to these examples.

Long-term psychological effects of the death of a close relative

Lehman *et al.* (1987) attempted to estimate the long-term psychological effects of the sudden death of a spouse or a child in a car crash. Starting with 80 bereaved spouses and parents, they paired 80 similar individuals who were not bereaved – that is, 80 matched controls – drawn from 7581 individuals who came to renew a drivers license, matching for gender, age, family income before the crash, education level, and number and ages of children. Contrasting their findings with the views of Bowlby and Freud, who had claimed bereavement has brief effects, they concluded:

Contrary to what some early writers have suggested about the duration of the major symptoms of bereavement ... both spouses and parents in our study showed clear evidence of depression and lack of resolution at the time of the interview, which was 5 to 7 years after the loss occurred.

Effects on children of occupational exposures to lead

Morton *et al.* (1982) asked whether children were harmed by lead brought home in the clothes and hair of parents who were exposed to lead at work. They matched children whose parents worked in a battery factory to unexposed control children of the same age and neighborhood, comparing the level of lead found in the children's blood, finding elevated levels of lead in exposed children.

In addition, they compared exposed children whose parents had varied levels of exposure to lead at the factory, finding that parents who had higher exposures on the job, in turn, had children with more lead in their blood. Finally, they compared exposed children whose parents had varied hygiene upon leaving the factory at the end of the day, finding that poor hygiene of the parent predicted higher levels of lead in the blood of the child.

Central Issues

Without random assignment of treatments, treated and control groups may not have been comparable prior to treatment; therefore, differing outcomes may reflect either biases from these pretreatment differences or effects actually caused by the treatment. The difficulty in distinguishing treatment effects from biases is the key consequence of the absence of randomization.

*With permission of the publisher, this article uses material from Rosenbaum, P. R. (2001). Observational Studies: Overview. In Smelser, N. and Baltes, P. (eds.) *International Encyclopedia of Social and Behavioral Sciences*, pp 10810–10815. New York: Elsevier.

A variable measured prior to treatment is not affected by the treatment and is called a covariate. A variable measured after treatment may have been affected by the treatment and is called an outcome. An analysis that does not carefully distinguish covariates and outcomes can introduce biases into the analysis where none existed previously (Rosenbaum, 1984).

A pretreatment difference between treated and control groups is called an overt bias if it is accurately measured in the data at hand, and it called a hidden bias if it is not measured. For instance, if treated subjects are observed to be somewhat older than controls, and if age is recorded, then this is an overt bias. If treated subjects consumed more illegal narcotics than controls, and if accurate records of this are not available, then this is a hidden bias. Typically, overt biases are immediately visible in the data at hand, while hidden biases are a matter of concerned speculation and investigation.

In most observational studies, an effort is made to remove overt biases using one or more analytical methods, such as matched sampling, stratification, or model-based adjustments such as covariance adjustment. Adjustments are discussed in the section titled 'Adjusting for overt bias'. Once this is accomplished, attention turns to addressing possible hidden biases, including efforts to detect hidden biases and to study the sensitivity of conclusions to biases of plausible magnitude. Hidden biases are discussed in the section title 'Detecting hidden bias', 'Sensitivity to hidden bias', and 'Reducing Sensitivity to hidden bias'.

Adjusting for Overt Biases

Matched Sampling

Selecting from a reservoir of potential controls

Matching is the most direct and intuitive method of adjustment, in which an effort is made to compare each treated individual to one or more comparable controls. Matched sampling is most common when a small treated group is available together with a large reservoir of potential controls (Rubin, 1979). For instance, in the study of bereavement by Lehman *et al.* (1987), there were 80 bereaved spouses and parents and 7581 potential controls, from whom 80 matched controls were selected.

The structure of the bereavement study is typical: computerized administrative records aid in identifying and matching treated and control subjects, but additional information is required from matched subjects for research purposes; in this case, psychiatric outcomes are required. Often, it is not practical to obtain the needed research data from all controls in the reservoir and, instead, a sample of controls is used. Matched sampling selects controls who appear comparable to treated subjects.

Goals of matching

Matching attempts to do three things: (1) produce matched pairs or sets that appear similar in terms of observed covariates, (2) produce treated and control groups with similar distributions of observed covariates, and (3) remove that part of the bias in estimated treatment effects that is due to overt biases or imbalances in observed covariates. For instance, with pairs matched for age, goal (1) would be accomplished if each treated subject were matched to a control of the same age, whereas goal (2) would be accomplished if the entire treated group had an age distribution that closely resembled the age distribution in the matched control group, for instance, the same mean age, the same quartiles of the age distribution, and so on.

It is possible to demonstrate (Rosenbaum and Rubin, 1983, theorem 4) that goal (1) suffices, but is not necessary for goal (2), and that goal (2) suffices for goal (3). Pairs that are individually matched for age will balance age; however, it is also possible to balance age with matched pairs that are not individually matched for age, and any matching that balances the distribution of age removes the part of the bias in estimated treatment effects due to imbalances in age. This is fortunate because it is difficult to match individually on many covariates at once, but it is not so difficult to balance many covariates at once. Modern matching algorithms focus on balancing covariates, while comparability within pairs plays a secondary role. A tool in balanced matching is the propensity score.

Propensity score

The propensity score is the conditional probability of receiving the treatment rather than the control, given the observed covariates (Rosenbaum and Rubin, 1983). Note carefully that the propensity score is defined in terms of the observed covariates even if there may be hidden biases due to unobserved covariates. In the simplest randomized experiment, treatment or control is assigned by the flip of a fair coin, and the propensity score equals 1/2 for all subjects no matter what covariates are observed. In an observational study, subjects with certain observed characteristics may be more likely to receive either treatment or control; therefore, the propensity score varies with these observed characteristics.

Matching on one variable, namely the propensity score, is often practical and tends to balance all of the observed covariates. Matching on the propensity score together with a few other observed covariates – say, matching on the propensity score together with age and gender – also tends to balance all of the observed covariates. If it suffices to adjust for the observed covariates – that is, if there is no hidden bias due to unobserved covariates – then it also suffices to adjust for the propensity score alone. These results are theorems 1 through 4 of Rosenbaum and Rubin (1983). In practice, the propensity

score is unknown and must be estimated, perhaps using a logit regression of treatment on covariates.

Structure of matched sets

Although pair matching is common, matching with multiple controls may reduce the standard error of the estimated treatment effect (Smith, 1997). Haviland *et al.* (2008) match with two controls in a study of the effects on teens of joining a gang.

It is not necessary to match every treated subject to the same fixed number of controls. In terms of bias reduction, the optimal form is a full matching in which each matched set may have one treated subject and several controls or one control and several treated subjects (Rosenbaum, 2002; § 10). In this way, when a certain pattern of observed covariates is typical of controls, then a treated subject with this pattern will have several controls; however, if, instead, the pattern is typical of treated subjects, several treated subjects may share one control. Hansen (2004) used full matching in an observational study of the effects of coaching on Scholastic Aptitude Test (SAT) scores.

Matching algorithms

Matching algorithms often express the difference in covariate values between a treated subject and a potential control in terms of a distance. Optimal matching minimizes the total distance within matched sets by solving what is known as a minimum cost flow problem, that is, a mathematical problem which originated in the field of operations research. The use of optimal matching in observational studies is discussed in Rosenbaum (2002, §10) and Hansen's (2007) implementation, called *optmatch*, is freely available in the statistical package R (R Development Core Team, 2007).

Matching and thick description

Since matching focuses attention on comparable pairs or sets of individuals under alternative treatments, it is straightforward to combine a quantitative study of many matched pairs with a qualitative study of a small subset of the matched pairs (Rosenbaum and Silber, 2001). For instance, quantitative results about all pairs might be reported along with narrative or thick descriptions of a few pairs.

Stratification

An alternative to matching is stratification, in which subjects are grouped into strata. Rosenbaum and Rubin (1983) balanced 74 covariates using five strata formed from an estimated propensity score. The optimal stratification – that is, the stratification that makes treated and control subjects as similar as possible within strata – is a full matching as described in the section entitled 'Structure of matched sets'. See Rosenbaum (2002, §10) for proof and

specifics, and Hansen (2007) for implementation of full matching in R.

Model-Based Adjustments

Matched sampling and stratification compare treated subjects directly to actual controls who appear comparable in terms of observed covariates. For instance, as noted earlier, Lehman *et al.* (1987) compared bereaved individuals to matched controls who were comparable in terms of age, gender, income, education, and family structure. In contrast, model-based adjustments, such as covariance adjustment, use data on treated and control subjects without regard to their comparability, relying on a model, such as a linear regression model, to predict how subjects would have responded under treatments they did not receive.

In simulation studies, Rubin (1979) compared matching, covariance adjustment, and combinations of these techniques, concluding that the use of covariance adjustment within matched pairs was superior to either method alone, being both robust and efficient. Dehejia and Wahba (1999) illustrate the hazards of model-based adjustments in the absence of matching.

Detecting Hidden Bias

In an observational study, the investigator takes active steps to detect hidden biases – to collect data recording visible traces of unobserved pretreatment differences, if they exist. In this, the investigator is aided by an elaborate theory, defined by Sir Ronald Fisher in the following discussion from Cochran (1965, 85).

About 20 years ago, when asked in a meeting what can be done in observational studies to clarify the step from association to causation, Sir Ronald Fisher replied: "Make your theories elaborate." The reply puzzled me at first, since by Occam's razor, the advice usually given is to make theories as simple as is consistent with known data. What Sir Ronald meant, as subsequent discussion showed, was that when constructing a causal hypothesis one should envisage as many different consequences of its truth as possible, and plan observational studies to discover whether each of these consequences is found to hold.

Consider the study of lead exposures by Morton *et al.* (1982), discussed in the section titled 'Effects on children of occupational exposures to lead'. Their elaborate theory made three predictions: (1) higher lead levels in the blood of exposed children than in matched control children, (2) higher lead levels in exposed children whose parents had higher exposure on the job, and (3) higher lead levels in exposed children whose parents practiced poorer hygiene upon leaving the factory. Since each of these predictions was consistent with observed data, to attribute

the observed associations to hidden bias, rather than an actual effect of lead exposure, one would need to postulate biases that could produce all three associations. Additionally, these observations are consistent with other studies of lead exposure. The use of elaborate theories and further examples are discussed in Shadish *et al.* (2002) and Rosenbaum (2002, 2004).

The simplest and most common design to detect hidden bias uses two control groups. Since neither control group received the treatment, systematic differences between the control groups cannot be effects of the treatment and must instead be some form of hidden bias. One seeks two control groups that would differ in their outcomes if a specific unobserved bias were present. In this way, hidden biases should produce a difference between the two control groups, whereas an actual treatment effect should produce relatively similar results in the two control groups and a different result in the treated group; see Campbell (1969), Meyer (1995), and Rosenbaum (2002, § 8).

Sensitivity to Hidden Bias

The analytical adjustments discussed in the section entitled ‘Adjusting for overt biases’ can often remove overt biases accurately recorded in the data at hand, but there is typically a legitimate concern that treated and control groups differed prior to treatment in ways that were not recorded. A sensitivity analysis asks how such hidden biases might alter the conclusions of the study.

The first formal method of sensitivity analysis was developed to aid in appraising the effects of cigarette smoking on human health. Responding to objections that smoking might not cause lung cancer, but rather that there might be a genetic predisposition both to smoke and to develop lung cancer, Cornfield *et al.* (1959: 40) wrote:

... if cigarette smokers have 9 times the risk of nonsmokers for developing lung cancer, and this is not because cigarette smoke is a causal agent, but only because cigarette smokers produce hormone X, then the proportion of hormone X-producers among cigarette smokers must be at least 9 times greater than among nonsmokers.

This statement was an important conceptual advance. It is, of course, commonly understood that association does not imply causation – that any observed association can be explained by a hypothetical argument, perhaps an implausible hypothetical argument, postulating an unobserved variable. Although this common understanding is always correct, it contributes little to our appraisal of an observational study because it makes no reference to what was actually observed in this empirical investigation, and no reference to scientific knowledge about the phenomenon under study (Bross, 1960). A sensitivity analysis replaces

the statement – association does not imply causation – by a specific statement about the magnitude of hidden bias that would need to be present to explain the associations actually observed. Strong associations in large studies can only be explained by large, perhaps implausible, biases. Aspects of the method of Cornfield *et al.* (1959) are discussed by Greenhouse (1982) and Gastwirth (1992). Although important as a conceptual advance, this method of sensitivity analysis is limited in that it ignores sampling error produced by having a finite sample rather than the population as a whole, and it is applicable only to binary outcomes. Rosenbaum (2002, §4) discusses a related method of sensitivity analysis that addresses sampling error and may be used with outcome measures of all kinds. See Imbens (2003) and Diprete and Gangl (2004) also.

Reducing Sensitivity to Hidden Bias

The Goal: Sharper Effects, Smaller Biases

Given the choice, one would prefer conclusions insensitive to hidden biases, so that there is less ambiguity about the effects caused by the treatment. A general quantitative tool for investigating the impact of the design of an observational study on its sensitivity to unobserved biases is the design sensitivity (Rosenbaum, 2004). This section discusses three strategies, namely, choice of circumstances, coherent hypotheses, and reducing unit heterogeneity.

Choice of circumstances

In the earliest stages of planning an observational study, the investigator chooses the circumstances in which the study will be conducted. These choices often affect both the size of the treatment effect and the magnitude of hidden bias that is plausible. As a result, these choices affect the sensitivity of the study to hidden bias. Some illustrations of this use of choice will be briefly mentioned. See Rosenbaum (2002, §11) for detailed discussion of these cases and others with examples, and see Meyer (1995) and Angrist and Kreuger (2001) for related discussion.

The investigator examines a broad research hypothesis, one that makes predictions about innumerable circumstances, but examines that hypothesis in particular circumstances where dramatic effects are anticipated, free of distortions from other factors that affect these same outcomes. The investigator seeks a situation in which there is a genuine control group completely shielded from the treatment, and a treated group that received the treatment at an intense dose. One prefers a treatment that is imposed suddenly, not gradually, and haphazardly, not in direct response to characteristics of the individuals under study.

For instance, in the study in the section entitled ‘Long-term psychological effects of the death of a close relative’

by Lehman *et al.* (1987), the effects of bereavement were studied following sudden deaths of close relatives from car crashes. Moreover, employing standardized criteria, they used only those car crashes for which the victim's car was not responsible, reasoning that alcohol or drug abuse or certain forms of psychopathology might increase the risk of a car crash and also be associated with unfavorable psychological outcomes in the family.

As another example, Angrist and Lavy (1999) studied the effects of class size on academic achievement in carefully chosen circumstances. In Israel, a rule dating back to Maimonides requires classrooms with no more than 40 students; therefore, a class with 41 students is divided in two classes of about 20 students. Whereas in the United States, a class of size 40 is likely to be found in a different economic environment from a class of size 20, in Israel, a comparatively haphazard event – the enrollment of an additional child – often separates these two situations.

Coherent hypotheses

A coherent hypothesis makes many highly specific predictions about the effect of a treatment on several outcome variables, perhaps in several treatment groups, probably involving one or more dose–response relationships. Sir Austin Bradford Hill (1965) claimed coherence as an important criterion in appraising evidence that a treatment is the cause of the outcomes with which it is associated. Coherence is related to pattern matching as discussed by Trochim (1985) and Shadish *et al.* (2002).

Informally, one feels that if numerous predictions of a causal theory are simultaneously confirmed, it should be more difficult to attribute this to hidden bias – the study should be less sensitive to bias. This is sometimes true, sometimes false, but when it is true, the reduction in sensitivity to bias can, in principle, be substantial. See Rosenbaum (2002, §9, 2004) and the references there for discussion.

Heterogeneity and causality

Consider two observational studies, one with a larger sample size but more heterogeneous units or individuals, the other with a smaller sample size but less heterogeneous units. Here, heterogeneity refers to the variability in outcomes after adjustment for observed covariates, say the variability in treated-minus-control differences in pairs matched for observed covariates. In a randomized experiment, the larger sample size in the first study might offset its greater variability, so that the two studies are essentially equivalent, say producing confidence intervals of the same length or hypothesis tests with the same power. In contrast, in observational studies, the smaller, less heterogeneous study will typically be better, in the sense that a treatment effect of the same magnitude in the two studies will be less sensitive to unobserved biases in this study (Rosenbaum, 2005). For instance, Ashenfelter

and Rouse (1998) compared the earnings of identical twins with different education, and Card and Krueger (1994) compared Burger Kings affected by a change in minimum wage laws to Burger Kings in an adjacent state that were unaffected. Other examples are discussed in Rosenbaum (2005).

Conclusion

An observational study examines the effects of a treatment in a context in which random assignment of subjects to treatment or control is infeasible for ethical or practical reasons. Unlike a randomized experiment, in an observational study, treated and control groups may not be comparable prior to treatment; therefore, differing outcomes after treatment may not be effects caused by the treatment. If the treated and control groups differ in ways that have been accurately measured, then adjustments are often possible, for instance, by matching treated subjects to controls who are similar in terms of measured pretreatment covariates. Invariably, there is the concern that some important covariate has not been measured; therefore, adjustments for measured covariates may fail to render the groups comparable. Addressing this concern is a central task in the design and analysis of an observational study. One tactic tries to detect bias from unmeasured covariates, for instance, with the aid of two control groups. A second tactic uses sensitivity analysis to appraise how biases of various magnitudes might alter the conclusions. A third tactic tries to design the study to reduce its sensitivity to unobserved biases. The most convincing studies use these tactics together so that each one removes some of the ambiguities left by the others.

Glossary

Censored sample – A sample appearing in the life-testing experiments when n items are kept under observation and only part of this sample can be observed.

Counting process – A stochastic process representing the total number of certain event occurring up to time.

Distribution free statistics for a class of distribution function – A statistic whose distribution is the same for all distribution function in the class.

Empirical distribution function – A natural estimation of the cumulative distribution function constructed on the base of the sample.

Extreme order statistics – The maximal and minimal order statistics.
